# Résumé

La programmation par passage de destination introduit le concept de *destination*, qui représente l'adresse d'une cellule mémoire encore vierge sur laquelle on ne peut écrire qu'une fois. Ces destinations peuvent être passées en tant que paramètres de fonction, permettant à l'appelant de garder le contrôle de la gestion mémoire : la fonction appelée se contente de remplir la cellule au lieu d'allouer de l'espace pour une valeur de retour. Bien que principalement utilisé en programmation système, le passage de destination trouve aussi des applications en programmation fonctionnelle pure, où il permet d'écrire des programmes auparavant inexpressibles avec les structures de données immuables usuelles.

Dans cette thèse, nous développons un  $\lambda$ -calcul avec destinations,  $\lambda_d$ . Ce nouveau système théorique est plus expressif que les travaux similaires existants, le passage de destination y étant conçu pour être aussi flexible que possible. Cette expressivité est rendue possible par un système de types modaux combinant types linéaires et un système d'âges pour gérer le contrôle lexical des ressources, afin de garantir la sûreté du passage de destination. Nous avons prouvé la sûreté de notre système via les théorèmes habituels de progression et de préservation des types, de façon mécanisée, avec l'assistant de preuve Coq.

Nous montrons ensuite comment le passage de destination, formalisé dans ce calcul théorique, peut être intégré à un langage fonctionnel pur existant, Haskell, dont le système de types est moins puissant que notre système théorique. Préserver la sûreté nécessite alors de restreindre la flexibilité dans la gestion des destinations. Nous affinons par la suite l'implémentation pour retrouver une grande partie de cette flexibilité, au prix d'une complexité accrue pour l'utilisateur.

L'implémentation prototype en Haskell montre des résultats encourageants pour l'adoption du passage de destination pour des parcours ou du mapping de grandes structures de données, telles que les listes ou les arbres.

# Abstract

Destination-passing style programming introduces destinations, which represent the address of a write-once memory cell. These destinations can be passed as function parameters, allowing the caller to control memory management: the callee simply fills the cell instead of allocating space for a return value. While typically used in systems programming, destination passing also has applications in pure functional programming, where it enables programs that were previously unexpressible using usual immutable data structures.

In this thesis, we develop a core  $\lambda$ -calculus with destinations,  $\lambda_d$ . Our new calculus is more expressive than similar existing systems, with destination passing designed to be as flexible as possible. This is achieved through a modal type system combining linear types with a system of ages to manage scopes, in order to make destination-passing safe. Type safety of our core calculus was proved formally with the Coq proof assistant.

Then, we see how this core calculus can be adapted into an existing pure functional language, Haskell, whose type system is less powerful than our custom theoretical one. Retaining safety comes at the cost of removing some flexibility in the handling of destinations. We later refine the implementation to recover much of this flexibility, at the cost of increased user complexity.

The prototype implementation in Haskell shows encouraging results for adopting destination-passing style programming when traversing or mapping over large data structures such as lists or data trees.

# Introduction

## 1 Memory management: a core design axis for programming languages

Over the last fifty years, programming languages have evolved into indispensable tools, profoundly shaping how we interact with computers and process information across almost every domain. Much like human languages, the vast variety of programming languages reflects the diversity of computing needs, design philosophies, and objectives that developers and researchers have pursued. This diversity is a response to specialized applications, user preferences, and the continuous search for improvements in either speed or expressiveness. Today, hundreds of programming languages exist, each with unique features and tailored strengths, making language selection a nuanced process for developers.

At a high level, programming languages differ in how they handle core aspects of data representation and program execution, and they can be classified along several key dimensions. These dimensions often reveal the underlying principles of the language and its suitability for different types of applications. Some of the main characteristics that distinguish programming languages include:

- how the user communicates intent to the computer —whether through explicit step-by-step instructions in procedural languages or through a more functional/declarative style that emphasizes what to compute rather than how;
- the organization and manipulation of data —using either object-oriented paradigms that encapsulate domain data within objects that can interact with each other or using simpler data structures that can be operated on and dissected by functions and procedures;
- the level of abstraction —a higher-level language abstracts technical details to enable more complex functionality in fewer lines of code, while lower-level languages provide more control over the environment and the detailed execution of a task;
- the management of memory —whether memory allocation and deallocation are handled automatically by the language, or require explicit intervention from the programmer;
- side effects and exceptions —whether they can be represented, caught, and/or manipulated with the language.

Among these, memory management is one of the most critical aspects of programming language design. Every program requires memory to store data and instructions, and this memory must be managed judiciously to prevent errors and maintain performance. Typically, programs operate with input sizes and data structures that can vary greatly, requiring dynamic

memory allocation to ensure smooth execution. Therefore, the chosen memory management scheme will shape very deeply how programmers write and structure their code but also which features can be included in the language with reasonable effort.

High-level languages, such as Python or Java, often manage memory automatically, through garbage collection. With automatic garbage collection (thanks to a tracing or reference-counting garbage collector), memory allocation and deallocation happen behind the scenes, freeing developers from the complexities of manual memory control. This automatic memory management simplifies programming, allowing developers to focus on functionality and making the language more accessible for rapid development. Although garbage collection is decently fast overall, it can be slow for some specific use-cases, and is also dreaded for its unpredictable overhead or pauses in the program execution, which makes it unsuited for real-time applications.

In contrast, low-level languages like C or Zig tend to provide developers with direct control over memory allocation and deallocation. It indeed allows for greater optimization and efficient resource usage, particularly useful in systems programming or performance-sensitive applications. This control, however, comes with increased risks; errors like memory leaks, buffer overflows, and dangling pointers can lead to instability and security vulnerabilities if not carefully detected and addressed.

Interestingly, some languages defy these typical categorizations by providing precise memory control in the form of safe, high-level abstractions. Such languages let the user manage resource lifetimes explicitly while taking the responsibility of allocating and deallocating memory at the start and end of each resource's lifetime. The most well-known examples are smart pointers in C++ and the ownership model in Rust, whose founding principles are also known as *Scope-Bound Resource Management* (SBRM) or *Resource Acquisition is Initialization* (RAII). Initially applicable only to stack-allocated objects in early C++, SBRM evolved with the introduction of smart pointers for heap-allocated objects in the early 2000s. These tools have since become fundamental to modern C++ and Rust, significantly improving memory safety. In particular, Rust provides safety guarantees comparable to those of garbage-collected languages but without the garbage collection overhead, at the cost of a steep learning curve. This makes Rust suitable for both high-level application programming and low-level systems development, bridging a gap that was traditionally divided by memory management style.

## 2 Destination passing style: taking roots in the old imperative world

In systems programming, where fine control over memory is essential, the same memory buffer is often (re)used several times, in order to save up memory space and decrease the number of costly calls to the memory allocator. As a result, we don't want intermediary functions to allocate memory for the result of their computations. Instead, we want to provide them with a memory address in which to write their result, so that we can decide to reuse an already allocated memory slot or maybe write to a memory-mapped file, or RDMA buffer...

In practice, this means that the parent scope manages not only the allocation and deallocation of the function inputs, but also those of *the function outputs*. Output slots are passed to functions as pointers (or mutable references in higher-level languages), allowing the function to write directly into memory managed by the caller. These pointers, called out parameters or *destinations*, specify the exact memory location where the function should store its output.

This idea forms the foundation of destination-passing style programming (DPS): instead of letting a function allocate memory for its outputs, the caller provides it with write access to a pre-allocated memory space that can hold the function’s results. Assigning memory responsibility to the caller, rather than the callee, makes functions more flexible to use: this is the core advantage of destination-passing style programming (DPS).

In a low-level, system-programming setting, DPS also offers direct performance benefits. For example, a large memory block can be allocated in advance and divided into smaller segments, each designated as an output slot for a specific function call. This minimizes the number of separate allocations required, which is often a performance bottleneck, especially in contexts where memory allocation is intensive.

In the functional interpretation of DPS that will follow, the memory saving will be more subtle, and we will instead leverage instead the flexibility and expressivity benefits of DPS to lift some usual limitations of functional programming.

### 3 Functional programming languages

Functional programming languages are often seen as the opposite end of the spectrum from systems languages.

Functional programming lacks a single definition, but most agree that a functional language:

- supports lambda abstractions, a.k.a. functions as first-class values, that can capture parts of their parent environment (closures), can be stored, and can be passed as parameters;
- emphasizes expressions over statements, where each instruction always produces a value;
- builds complex expressions by applying and composing functions rather than chaining statements.

From these principles, functional languages tend to favor immutable data structures and a declarative style, where new data structures are defined by specifying their differences from existing ones, often relying on structural sharing and persistent data structures instead of direct mutation.

Since “everything is an expression” in functional languages, they are particularly amenable to mathematical formalization. This is no accident: many core concepts in functional programming originate in mathematics, such as  $\lambda$ -calculus —a minimal yet fully expressive model of computation, that also connects closely with formal proofs through the Curry-Howard isomorphism.

Despite this, many functional languages still permit expressions with side effects. Side effects encompass all the observable actions a program can take on its environment, e.g. writing to a file, or to the console, or altering memory. Side effects are hard to reason about, especially if any expression of the language is likely to emit one, but they are in fact a very crucial piece of any programming language: without them, there is no way for a program to communicate its results to the “outside”.

**Pure functional programming languages** Some functional languages enforce a stricter approach by disallowing side effects except at the boundaries of the main program, a concept known as *pure functional programming*. Here, all programmer-defined expressions compute and return values without side effects. Instead, the *intention* of performing side effects (like printing to the console) can be represented as a value, which is only turned into the intended side effect by the language runtime.

This restriction provides substantial benefits. Programs can be wholly modeled as mathematical functions, making reasoning about behavior easier and allowing for more powerful analysis of a program’s behavior.

A key property of pure functional languages is *referential transparency*: any function call can be substituted with its result without altering the program’s behavior. This property is obviously absent in languages like C; for example, replacing `write(myfile, string, 12)` with the value `12` (its return if the write is successful) would not produce the intended behavior: the latter would not produce any write effect at all.

This ability to reason about programs as pure functions greatly improves the predictability of programs, especially across library boundaries, and overall improves software safety.

**Memory management in functional languages** Explicit memory management is very often *impure*, as modifying memory in a way that can later be inspected *is* a side effect. Consequently, most functional languages (even those that aren’t fully *pure* like OCaml or Scala) tend to rely on a garbage collector to abstract away memory management and memory access for the user.

However, this doesn’t mean that functional languages must entirely give up any aspect of memory control; it simply means that memory control cannot involve explicit effectful statements like `malloc` or `free`. In practice, it requires that memory management should not affect the value of an expression being computed within the language. One way to achieve this is by using annotations or pragmas attached to specific functions or blocks of code, indicating how or where memory should be allocated. Another approach is to use a custom type system with *modes*, to track at type level how values are managed in memory, as in the recent modal development for OCaml [Lorenzen, White, et al., 2024]. Additionally, some languages use special built-in functions, like `oneShot` in Haskell, which do not affect the result of the expression they wrap around, but carry special significance for the compiler in managing memory.

There is also another possible solution. We previously mentioned that side effects —prohibited in pure functional languages— are any modifications of the environment or memory that are *observable* by the user. What if we allow explicit memory management expressions while ensuring that these (temporary) changes to memory or the environment remain unobservable?

This is the path we will adopt —one that others have taken before— allowing for finer-grained memory control while upholding the principles of purity.

## 4 Functional structures with holes: pioneered by Minamide and quite active since

In most contexts, functional languages with garbage collectors efficiently manage memory without requiring programmer intervention. However, a major limitation arises from the *immutability* characteristic common to most functional languages, which restricts us to constructing data structures directly in their final form. That means that the programmer has to give an initial value to every field of the structure, even if no meaningful value for them has been computed yet. And later, any update beyond simply expanding the original structure requires creating a (partial) copy of that structure. This incurs a big load on the allocator and garbage collector.

#### 4. Functional structures with holes: pioneered by Minamide and quite active since

As a result, algorithms that generate large structures —whether by reading from an external source or transforming an existing structure— might need many intermediate allocations, each representing a temporary processing state. While immutability has advantages, in this case, it can become an obstacle to optimizing performance.

To lift this limitation, Minamide [1998] introduced an extension for functional languages that allows to represent *yet incomplete* data structures, that can be extended and completed later. Incomplete structures are not allowed to be read until they are completed —this is enforced by the type system— so that the underlying mutations that occur while updating the structure from its incomplete state to completion are hidden from the user, who can only observe the final result. This way, it preserves the feel of an immutable functional language and doesn’t break purity per se. This method of making imperative or impure computations opaque to the user by making sure that their effects remain unobservable to the user (thanks to type-level guarantees) is central to the approach developed in this document.

In Minamide’s work, incomplete structures, or *structures with a hole*, are represented by hole abstractions —essentially pure functions that take the missing component of the structure as an argument and return the completed structure. In other terms, it represents the pending construction of a structure, than can theoretically only be carried out when all its missing pieces have been supplied. Hole abstractions can also be composed, like functions:  $(\lambda x \mapsto 1 :: x) \circ (\lambda y \mapsto 2 :: y) \rightsquigarrow \lambda y \mapsto 1 :: 2 :: y$ . Behind the scenes however, each hole abstraction is not represented in memory by a function object, but rather by a pair of pointers, one read pointer to the root of the data structure that the hole abstraction describes, and one write pointer to the yet unspecified field in the data structure. Composition of two holes abstractions can be carried out immediately, with no need to wait for the missing value of the second hole abstraction, and results, memory-wise, in the mutation of the previously missing field of the first one, to point to the root of the second one.

In Minamide’s system, the (pointer to the) hole and the structure containing it are indissociable. One interacts with the hole in the structure by interacting with the structure itself, which limits an incomplete structure to having only a single hole. For these reasons, we would argue that Minamide’s approach does not yet qualify as destination-passing style programming. Nonetheless, it is one of the earliest examples of a pure functional language allowing data structures to be passed with write permissions while preserving key language guarantees such as memory safety and purity.

This idea has been refreshed and extended more recently with [Leijen and Lorenzen, 2025] and [Lorenzen, Leijen, Swierstra, and Lindley, 2024], where structures with holes are referred to as *first-class contexts*.

To reach true destination-passing style programming however, we need a way to refer to the hole(s) of the incomplete structure without having to pass around the structure that has the hole(s). This in fact hasn’t been explored much in functional settings so far. [Bour, Clément, and Scherer, 2021] is probably the closest existing work on this matter, but destination-passing style is only used at the intermediary language level, in the compiler, to do optimizations, so the user can’t make use of DPS in their code.

## 5 Unifying and formalizing Functional DPS frameworks

What we’ll develop on in this thesis is a functional language in which *structures with holes* are a first-class type in the language, as in [Minamide, 1998], but that also integrate first-class *pointers to these holes*, aka. *destinations*, as part of the user-facing language.

We’ll see that combining these two features gives us performance improvement for some functional algorithms like in [Bour, Clément, and Scherer, 2021] or [Leijen and Lorenzen, 2025], but we also get some extra expressiveness that is usually a privilege of imperative languages only. It should be indeed the first instance of a functional language that supports write pointers in the frontend (and not only in intermediate representation like [Bour, Clément, and Scherer, 2021; Leijen and Lorenzen, 2025]) to make flexible and efficient data structure building!

In fact, we will design a formal language in which *structures with holes* serve as the core abstraction for constructing data structures, departing from the traditional use of data constructors in functional programming. Later, we will demonstrate how many of the ideas and features from this theoretical calculus can be implemented in a practical functional language —namely Haskell— while retaining as much expressivity as possible. We will also show that the predicted benefits of the approach are effectively observed in the prototype Haskell implementation.

The formal language will also aim at providing a theoretical framework that encompasses most existing work on functional DPS and can be used to reason about safety and correctness properties of earlier works.

## 6 Reconciling write pointers and immutability

Introducing unrestricted write pointers in a functional setting would not play well as it would break many properties that make functional languages easy to reason about. Instead, we need tools to ensure that only controlled mutations occur. The goal is to allow a structure to remain partially uninitialized temporarily, with write pointers referencing these uninitialized portions. However, once the structure has been fully populated, with a value assigned to each field, it should become immutable to maintain the integrity of the functional paradigm. Put simply, we need a write-once discipline for fields within a structure, which can be mutated through their associated write pointers aka. *destinations*. While enforcing a single-use discipline for destinations at runtime would be unwieldy, we can instead deploy static guarantees through the type system to ensure that every destination will be used exactly once.

In programming language theory, when new guarantees are required, it’s common to design a type system to enforce them, ensuring the program remains well-typed. This is precisely the approach we’ll take here, facilitated by an established type system —*linear types*— which can monitor resource usage, especially the number of times a resource is used. Leveraging a linear type system, we can design a language in which structures with holes are first-class citizens, and write pointers to these holes are only usable once. This ensures that each hole is filled exactly once, preserving immutability and making sure that structure are indeed completed before being read.

# Chapter 1

## Linear $\lambda$ -calculus and Linear Haskell

In the following we assume that the reader is familiar with the simply-typed  $\lambda$ -calculus, its typing rules, and usual semantics. We also assume some degree of familiarity with the intuitionistic fragment of natural deduction. We kindly refer the reader to [Pierce, 2002] and [Sørensen and Urzyczyn, 2006] for a proper introduction to these notions.

### 1.1 From $\lambda$ -calculus to linear $\lambda$ -calculus

At the end of the 1930s, Alonzo Church introduced the *untyped  $\lambda$ -calculus* as a formal mathematical model of computation. Untyped  $\lambda$ -calculus is based on the concept of function abstraction and application, and is Turing-complete: in other terms, it has the same expressive power as the rather imperative model of *Turing machines*, introduced in the same decade. The only available objects in the untyped  $\lambda$ -calculus are pure functions; but they can be used smartly to encode many other kind of data, and as a result they are enough to form a solid model of computation.

In 1940, Church defined a typed variant of its original calculus, denoted *simply-typed  $\lambda$ -calculus*, or STLC, that gives up Turing-completeness but becomes strongly-normalizing: every well-typed term eventually reduces to a normal form. STLC assign types to terms, and restricts the application of functions to terms of the right type. This restriction is enforced by the typing rules of the calculus.

It was observed by Howard in 1969 [Howard, 1969] that the simply-typed  $\lambda$ -calculus is actually isomorphic to the logical framework known as *natural deduction*. This observation relates to earlier work by Curry, who had also noted similar symmetries between systems on the computational side and those on the logical side. These insights were later formalized into the *Curry-Howard isomorphism*, which states that types in a typed  $\lambda$ -calculus correspond to formulae in a proof system, and that terms correspond to proofs of these formulae. The Curry-Howard isomorphism has since been extended to other logics and calculi and has been a rich source of inspiration for research on both the logical and computational sides. For instance, building on an idea from his work on models of the  $\lambda$ -calculus, Jean-Yves Girard first introduced Linear Logic [Jean-Yves Girard, 1987], and later the corresponding calculus, known as the *linear  $\lambda$ -calculus*.

**What is linear logic?** In some logical presentations, notably the sequent calculus<sup>1</sup>, hypotheses are duplicated or discarded explicitly using *structural* rules of the system, named respectively *contraction* and *weakening* (in contrast to natural deduction where all that happens implicitly, as it is part of the meta-theory). As a result, it is possible to track the number of times a formula is used by counting the use of these structural rules. In Linear Logic, contraction and weakening are deliberately restricted, so by default, every hypothesis must be used exactly once. Consequently, logical implication  $\mathbf{T} \rightarrow \mathbf{U}$  is not part of linear logic, but is replaced by linear implication  $\mathbf{T} \multimap \mathbf{U}$ , where  $\mathbf{T}$  must be used exactly once to prove  $\mathbf{U}$ . Linear logic also introduces a modality  $!$ , pronounced *of course* or *bang*, to allow weakening and contraction on specific formulae:  $!\mathbf{T}$  denotes that  $\mathbf{T}$  can be used an arbitrary number of times (we say it is *unrestricted*). We say that linear logic is a *substructural* logic because it restricts the use of structural rules of usual logic.

We present in Figure 1.1 a natural deduction formulation<sup>2</sup> of intuitionistic linear logic (ILL), as it lends itself well to a computational interpretation as a linear  $\lambda$ -calculus with usual syntax.

All the rules of ILL, except the ones related to the  $!$  modality, are directly taken (and slightly adapted) from natural deduction.  $\mathbf{1}$  denotes the truth constant,  $\oplus$  denotes disjunction, and  $\otimes$  denotes conjunction<sup>3</sup>. Hypotheses are represented by multisets  $\Gamma$ . These multisets keep track of how many times each formula appear in them. The comma operator in  $\Gamma_1, \Gamma_2$  is multiset union, so it sums the number of occurrences of each formula in  $\Gamma_1$  and  $\Gamma_2$ . We denote the empty multiset by  $\bullet$ .

Let's focus on the four rules for the  $!$  modality now. The promotion rule ILL/!P states that a formula  $\mathbf{T}$  can become an unrestricted formula  $!\mathbf{T}$  if it only depends on formulae that are themselves unrestricted. For this purpose, we introduce the notation  $!\Gamma$  to denote a context which contains the same hypotheses as  $\Gamma$  but all wrapped in the  $!$  modality in other terms, every hypothesis in the (potentially empty) multiset  $!\Gamma$  is unrestricted. The dereliction rule ILL/!D states that an unrestricted formula  $!\mathbf{T}$  can be used in a place expecting a linear formula  $\mathbf{T}$ . The contraction rule ILL/!C and weakening rule ILL/!W state respectively that an unrestricted formula  $!\mathbf{T}$  can be cloned or discarded at any time.

The linear logic system might appear very restrictive, but we can always simulate the usual non-linear natural deduction in ILL, through the  $!$  modality. Girard gives precise rules for such a translation in Section 2.2.6 of [J.-Y. Girard, 1995], whose main idea is to prefix most formulae with  $!$  and encode the non-linear implication  $\mathbf{T} \rightarrow \mathbf{U}$  as  $!\mathbf{T} \multimap \mathbf{U}$ .

To become more familiar with the system, let us explore how linear logic effectively restricts the duplication of linear hypotheses through its rules. For example, let's try (and fail) to derive the implication  $\mathbf{T} \multimap (\mathbf{T} \otimes \mathbf{T})$  from an empty environment:

<sup>1</sup>Sequent calculus is a very popular logic framework that is an alternative to natural deduction and that has also been introduced by Gentzen in the 30s

<sup>2</sup>Though we borrow the *sequent style* notation of sequent calculus for easier transition into typing rules of terms later. However, as we are in an intuitionistic setting, rules only derive a single conclusion from a multiset of formulae.

<sup>3</sup>Linear logic distinguishes between multiplicative and additive conjunctions and disjunctions, which differ in how they interact with negation and De Morgan duality: multiplicative connectives (e.g.,  $\otimes$ ,  $\wp$ ) are dual to each other, as are additive ones (e.g.,  $\oplus$ ,  $\&$ ). In our setting, we focus on  $\otimes$  (multiplicative conjunction) and  $\oplus$  (additive disjunction), as they correspond more closely to the standard logical connectives  $\wedge$  and  $\vee$ .

$$\boxed{\Gamma \vdash \top} \quad \text{(Deduction rules)}$$

$$\begin{array}{c}
\frac{}{\top \vdash \top} \text{ID} \quad \frac{\Gamma, \top \vdash \mathbf{U}}{\Gamma \vdash \top \multimap \mathbf{U}} \multimap\text{I} \quad \frac{}{\bullet \vdash \mathbf{1}} \mathbf{1}\text{I} \quad \frac{\Gamma \vdash \top_1}{\Gamma \vdash \top_1 \oplus \top_2} \oplus\text{I}_1 \quad \frac{\Gamma \vdash \top_2}{\Gamma \vdash \top_1 \oplus \top_2} \oplus\text{I}_2 \\
\\
\frac{\Gamma_1 \vdash \top_1 \quad \Gamma_2 \vdash \top_2}{\Gamma_1, \Gamma_2 \vdash \top_1 \otimes \top_2} \otimes\text{I} \quad \frac{\Gamma_1 \vdash \top \quad \Gamma_2 \vdash \top \multimap \mathbf{U}}{\Gamma_1, \Gamma_2 \vdash \mathbf{U}} \multimap\text{E} \quad \frac{\Gamma_1 \vdash \mathbf{1} \quad \Gamma_2 \vdash \mathbf{U}}{\Gamma_1, \Gamma_2 \vdash \mathbf{U}} \mathbf{1}\text{E} \\
\\
\frac{\Gamma_1 \vdash \top_1 \oplus \top_2 \quad \Gamma_2, \top_1 \vdash \mathbf{U}}{\Gamma_1, \Gamma_2 \vdash \mathbf{U}} \oplus\text{E} \quad \frac{\Gamma_1 \vdash \top_1 \otimes \top_2 \quad \Gamma_2, \top_1, \top_2 \vdash \mathbf{U}}{\Gamma_1, \Gamma_2 \vdash \mathbf{U}} \otimes\text{E} \quad \frac{! \Gamma \vdash \top}{! \Gamma \vdash ! \top} !\text{P} \quad \frac{\Gamma \vdash ! \top}{\Gamma \vdash \top} !\text{D} \quad \frac{\Gamma_1 \vdash ! \top \quad \Gamma_2, ! \top, ! \top \vdash \mathbf{U}}{\Gamma_1, \Gamma_2 \vdash \mathbf{U}} !\text{C} \\
\\
\frac{\Gamma_1 \vdash ! \top \quad \Gamma_2 \vdash \mathbf{U}}{\Gamma_1, \Gamma_2 \vdash \mathbf{U}} !\text{W}
\end{array}$$

Figure 1.1: Intuitionistic linear logic in natural deduction presentation, sequent-style (ILL)

$$\frac{\frac{\frac{}{\top \vdash \top} \text{ID} \quad \frac{}{\top \vdash \top} \text{ID}}{\top, \top \vdash \top \otimes \top} \otimes\text{I}}{\top \vdash \top \multimap (\top \otimes \top)} \multimap\text{I}$$

In sequent calculus, we would insert a contraction step between  $\otimes\text{I}$  and  $\multimap\text{I}$  to deduce  $\top \vdash \top \otimes \top$  from  $\top, \top \vdash \top \otimes \top$ . But in linear logic, contraction is not allowed for linear hypotheses. Each application of the ILL  $\multimap\text{I}$  rule consumes exactly one copy of  $\top$ , so we still need an extra  $\top$  in the context to make this implication work.

But all is not lost; we *can* duplicate a value if it comes wrapped in the  $!$  modality. That's precisely what  $!\top$  is for: an unrestricted version of  $\top$  that allows copying. So let's see how we can derive the implication  $!\top \multimap (\top \otimes \top)$  from an empty environment:

$$\frac{\frac{\frac{}{!\top \vdash !\top} \text{ID}}{!\top \vdash \top} !\text{D} \quad \frac{\frac{}{!\top \vdash !\top} \text{ID}}{!\top \vdash \top} !\text{D}}{\frac{\frac{}{!\top \vdash !\top} \text{ID} \quad \frac{!\top, !\top \vdash \top \otimes \top}{!\top \vdash \top \otimes \top} \otimes\text{I}}{!\top \vdash \top \otimes \top} !\text{C}}{\bullet \vdash !\top \multimap (\top \otimes \top)} \multimap\text{I}$$

Here, we use identity and dereliction to extract linear  $\top$ s from the unrestricted  $!\top$ . The product  $\top \otimes \top$  requires two copies, so we need two  $!\top$ s in the context; and that corresponds exactly to the setting required to apply the contraction rule ILL/ $!\text{C}$ . In the next section, we'll see how this derivation corresponds to a well-typed program.

$$\begin{aligned}

 \end{array}$$

Figure 1.3: Typing rules for linear  $\lambda$ -calculus in monadic presentation ( $\lambda_{L1\text{-TY}}$ )

## 1.2 Linear $\lambda$ -calculus: a computational interpretation of linear logic

There are several possible interpretations of linear logic as a linear  $\lambda$ -calculus. The first —referred to as the *monadic* presentation, following the terminology of [Andreoli, 1992]— arises from a direct term assignment to the natural deduction rules of ILL shown in Figure 1.1. The syntax and typing rules for this monadic formulation, denoted  $\lambda_{L1}$ , are presented in Figures 1.2 and 1.3, and are heavily inspired by the work of Bierman [1994].

### 1.3. Implicit structural rules for unrestricted resources

In  $\lambda_{L1}$ ,  $\Gamma$  is now a finite map from variables to types that can be represented as a set of variable bindings  $x : \mathbb{T}$ . As usual, duplicated variable names are not allowed in a context  $\Gamma$ . The comma operator now denotes disjoint union for finite maps.

Term grammar for  $\lambda_{L1}$  borrows most of simply-typed  $\lambda$ -calculus grammar. Elimination of unit type **1** is made with the  $\mathfrak{s}$  operator. Pattern-matching on sum and product types is made with the **case** keyword. Finally, we have new operators **dup**, **drop** and **derelict** for, respectively, contraction, weakening and dereliction of unrestricted terms with type  $\mathbb{T}$ . In addition, the language includes a data constructor for unrestricted terms and values, denoted by **Many**  $t$  and **Many**  $v$ . Promotion of a term to an unrestricted form is made by direct application of constructor **Many**. For easier exposition, we allow ourselves to use syntactic sugar **let**  $x := t$  **in**  $u$  and encode it as  $(\lambda x \mapsto u) (t)$ .

The derivation of the linear implication  $\mathbb{T} \multimap (\mathbb{T} \otimes \mathbb{T})$  from previous section now translates into a typing derivation for a well-typed term of type  $\mathbb{T} \multimap (\mathbb{T} \otimes \mathbb{T})$ . Let's see how it goes:

$$\begin{array}{c}
 \frac{}{x : \mathbb{T} \vdash x : \mathbb{T}} \text{ID} \quad \frac{}{x_1 : \mathbb{T} \vdash x_1 : \mathbb{T}} \text{ID} \quad \frac{}{x_2 : \mathbb{T} \vdash x_2 : \mathbb{T}} \text{ID} \\
 \frac{}{x_1 : \mathbb{T} \vdash \text{derelict } x_1 : \mathbb{T}} \text{!D} \quad \frac{}{x_2 : \mathbb{T} \vdash \text{derelict } x_2 : \mathbb{T}} \text{!D} \\
 \frac{}{x : \mathbb{T} \vdash x : \mathbb{T}} \text{ID} \quad \frac{}{x_1 : \mathbb{T}, x_2 : \mathbb{T} \vdash (\text{derelict } x_1, \text{derelict } x_2) : \mathbb{T} \otimes \mathbb{T}} \otimes \text{I} \\
 \frac{}{x : \mathbb{T} \vdash \text{dup } x \text{ as } x_1, x_2 \text{ in } (\text{derelict } x_1, \text{derelict } x_2) : \mathbb{T} \otimes \mathbb{T}} \text{!C} \\
 \frac{}{\bullet \vdash \lambda x \mapsto \text{dup } x \text{ as } x_1, x_2 \text{ in } (\text{derelict } x_1, \text{derelict } x_2) : \mathbb{T} \multimap (\mathbb{T} \otimes \mathbb{T})} \multimap \text{I}
 \end{array}$$

This translation is very direct. The only change is that we have to give distinct variable names to hypotheses of the same type inside the typing context, while there was no concept of named copies of a same formula in ILL. We also see that dealing with unrestricted hypotheses can be rather heavyweight because of the need of manual duplication and dereliction. Next section present a way to circumvent this issue.

### 1.3 Implicit structural rules for unrestricted resources

In the monadic presentation  $\lambda_{L1}$ , the use of unrestricted terms can become very verbose and cumbersome because of the need for explicit contraction, weakening and dereliction. A second and equivalent presentation of the linear  $\lambda$ -calculus, named *dyadic* presentation or  $\lambda_{L2}$ , tends to alleviate this burden by using two typing contexts on each judgment, one for linear variables and one for unrestricted variables. The syntax and typing rules of  $\lambda_{L2}$  are given in Figures 1.4 and 1.5.

In  $\lambda_{L2}$  there are no longer rules for contraction, weakening, and dereliction of unrestricted resources. Instead, each judgment is equipped with a second context  $\mathcal{U}$  that holds variable bindings that can be used in an unrestricted fashion. The **case**  $t$  **of** **Many**  $x \mapsto u$  construct let us access a term of type  $\mathbb{T}$  as a variable  $x$  of type  $\mathbb{T}$  that lives in the unrestricted context  $\mathcal{U}$ . It's important to note that **case**  $t$  **of** **Many**  $x \mapsto u$  is not dereliction: one can still use  $x$  several times within body  $u$ , or recreate  $t$  by wrapping  $x$  back as **Many**  $x$ ; while that wouldn't be possible with **let**  $x := \text{derelict } t$  **in**  $u$  of  $\lambda_{L1}$ . Morally, we can view the pair of contexts  $\Gamma; \mathcal{U}$  of  $\lambda_{L2}$  as a single context  $\Gamma, !\mathcal{U}$  of  $\lambda_{L1}$ , where  $!\mathcal{U}$  is the context with the same variable bindings as  $\mathcal{U}$ , except that all types are prefixed by  $!$ .

$v ::= \lambda x \mapsto u \mid () \mid \text{Inl } v \mid \text{Inr } v \mid (v_1, v_2) \mid \text{Many } v$   
 $t, u ::= v \mid x \mid \text{Inl } t \mid \text{Inr } t \mid (t_1, t_2) \mid \text{Many } t \mid t \mathbin{\text{\textcircled{;}}} t' \mid t \mathbin{\text{\textcircled{;}}} t'$   
 $\quad \mid \text{case } t \text{ of } \{\text{Inl } x_1 \mapsto u_1, \text{Inr } x_2 \mapsto u_2\} \mid \text{case } t \text{ of } (x_1, x_2) \mapsto u \mid \text{case } t \text{ of } \text{Many } x \mapsto u$   
 $\mathbb{T}, \mathbb{U} ::= \mathbb{T} \multimap \mathbb{U} \mid \mathbf{1} \mid \mathbb{T}_1 \oplus \mathbb{T}_2 \mid \mathbb{T}_1 \otimes \mathbb{T}_2 \mid !\mathbb{T}$   
 $\Gamma ::= \bullet \mid x : \mathbb{T} \mid \Gamma_1, \Gamma_2$   
 $\mathbb{U} ::= \bullet \mid x : \mathbb{T} \mid \mathbb{U}_1, \mathbb{U}_2$

 \end{array}$$

Figure 1.5: Typing rules for linear  $\lambda$ -calculus in dyadic presentation ( $\lambda_{L2}\text{-TY}$ )

### 1.3. Implicit structural rules for unrestricted resources

In  $\lambda_{L2}$ , contraction for unrestricted resources happens implicitly every time a rule has two subterms as premises. Indeed, the unrestricted context  $\mathcal{U}$  is duplicated in both premises, as we observe in particular in rule  $\lambda_{L2}\text{-TY}/\otimes\text{I}$ , unlike the linear context  $\Gamma$  that must be split into two disjoint parts. All unrestricted variable bindings are thus propagated to the leaves of the typing tree, that is, the rules with no premises  $\lambda_{L2}\text{-TY}/\text{ID}_{\text{LIN}}$ ,  $\lambda_{L2}\text{-TY}/\text{ID}_{\text{UR}}$ , and  $\lambda_{L2}\text{-TY}/\text{!I}$ . These three rules discard all bindings of the unrestricted context  $\mathcal{U}$  that aren't used, performing several implicit weakening steps.

Finally, this system has two identity rules. The first one,  $\lambda_{L2}\text{-TY}/\text{ID}_{\text{LIN}}$ , is the usual linear identity: it consumes the variable  $x$  present in the linear typing context. Because the linear typing context must be split into disjoint parts between sibling subterms (when a rule has several premises, like the product rule), it means  $x$  can only be used in one of them. The second identity rule,  $\lambda_{L2}\text{-TY}/\text{ID}_{\text{UR}}$ , is the unrestricted identity: it lets us use the variable  $x$  from the unrestricted typing context in a place where a linear variable is expected, performing a sort of implicit dereliction. Because the unrestricted typing context is duplicated between sibling subterms, an unrestricted variable can be used in several of them. For instance, the following derivation is *not valid* because we don't respect the disjointness condition of the comma operator for the resulting typing context of the pair:

$$\frac{\frac{}{x' : \mathbf{T} ; \bullet \vdash x' : \mathbf{T}} \text{ID}_{\text{LIN}} \quad \frac{}{x' : \mathbf{T} ; \bullet \vdash x' : \mathbf{T}} \text{ID}_{\text{LIN}}}{x' : \mathbf{T}, x' : \mathbf{T} ; \bullet \vdash (x', x') : \mathbf{T} \otimes \mathbf{T}} \otimes\text{I}$$

but the following derivation is valid, as the unrestricted typing context is duplicated between sibling subterms:

$$\frac{\frac{}{\bullet ; x' : \mathbf{T} \vdash x' : \mathbf{T}} \text{ID}_{\text{UR}} \quad \frac{}{\bullet ; x' : \mathbf{T} \vdash x' : \mathbf{T}} \text{ID}_{\text{UR}}}{\bullet ; x' : \mathbf{T} \vdash (x', x') : \mathbf{T} \otimes \mathbf{T}} \otimes\text{I}$$

At this point, we are very close from recreating a term of type  $\mathbf{T} \multimap (\mathbf{T} \otimes \mathbf{T})$  as we did in previous section. Let's finish the example:

$$\frac{\frac{}{x : \mathbf{T} ; \bullet \vdash x : \mathbf{T}} \text{ID}_{\text{LIN}} \quad \frac{\frac{}{\bullet ; x' : \mathbf{T} \vdash x' : \mathbf{T}} \text{ID}_{\text{UR}} \quad \frac{}{\bullet ; x' : \mathbf{T} \vdash x' : \mathbf{T}} \text{ID}_{\text{UR}}}{\bullet ; x' : \mathbf{T} \vdash (x', x') : \mathbf{T} \otimes \mathbf{T}} \otimes\text{I}}{x : \mathbf{T} ; \bullet \vdash \text{case } x \text{ of Many } x' \mapsto (x', x') : \mathbf{T} \otimes \mathbf{T}} \text{!E}}{\bullet ; \bullet \vdash \lambda x \mapsto \text{case } x \text{ of Many } x' \mapsto (x', x') : \mathbf{T} \multimap \mathbf{T} \otimes \mathbf{T}} \multimap\text{I}$$

If we had any useless variable binding polluting our unrestricted typing context (let's say  $\mathcal{U} = y : \mathbf{!U}$ ), the derivation would still hold without any change at term level; the useless bindings would just be carried over throughout the typing tree, and eliminated at the leaves (via implicit weakening happening in leaf rules):

$$\frac{\frac{}{x : \mathbf{T} ; y : \mathbf{!U} \vdash x : \mathbf{T}} \text{ID}_{\text{LIN}} \quad \frac{\frac{}{\bullet ; y : \mathbf{!U}, x' : \mathbf{T} \vdash x' : \mathbf{T}} \text{ID}_{\text{UR}} \quad \frac{}{\bullet ; y : \mathbf{!U}, x' : \mathbf{T} \vdash x' : \mathbf{T}} \text{ID}_{\text{UR}}}{\bullet ; y : \mathbf{!U}, x' : \mathbf{T} \vdash (x', x') : \mathbf{T} \otimes \mathbf{T}} \otimes\text{I}}{x : \mathbf{T} ; y : \mathbf{!U} \vdash \text{case } x \text{ of Many } x' \mapsto (x', x') : \mathbf{T} \otimes \mathbf{T}} \text{!E}}{\bullet ; y : \mathbf{!U} \vdash \lambda x \mapsto \text{case } x \text{ of Many } x' \mapsto (x', x') : \mathbf{T} \multimap \mathbf{T} \otimes \mathbf{T}} \multimap\text{I}$$

Managing unrestricted hypotheses is, as we just demonstrated, much easier in the dyadic system  $\lambda_{L2}$ . Typing trees are shorter, and probably easier to read too.

Also, we don't lose anything by going from  $\lambda_{L1}$  presentation to  $\lambda_{L2}$ : Andreoli [1992] has a detailed proof that  $\lambda_{L1}\text{-TY}$  and  $\lambda_{L2}\text{-TY}$  are equivalent, in other terms, that a program  $t$  types in the pair of contexts  $\Gamma; \bar{U}$  in  $\lambda_{L2}\text{-TY}$  if and only if it types in context  $\Gamma, !\bar{U}$  in  $\lambda_{L1}\text{-TY}$ .

## 1.4 Back to a single context with the graded modal approach

So far, we only considered type systems that are linear, but that are otherwise fairly standard with respect to usual simply-typed  $\lambda$ -calculus. Anticipating on our future needs, further in this document we'll need to carry more information and restrictions throughout the type system than just linearity alone.

Naively, we could just multiply the typing contexts, for each new modality that we need. The problem is, that approach is not really scalable: at the end we need one context per possible combination of modalities (if modalities represent orthogonal principles), so it grows really quickly.

In fact, without thinking too far away, we already have a problem if we want a finer control over linearity. What if we want to allow variables to be used a fixed number of times that isn't just one or unlimited? In [Jean-Yves Girard, Scedrov, and Scott, 1992], Girard considers the *bounded* extension of linear logic, where the number of uses of hypotheses can be restricted to any value  $m$ —named *multiplicity*—instead of being just linear or unrestricted. For that he extends the  $!$  modality with an index  $m$  that specifies how many times an hypothesis should be used. We say that  $!_m$  is a *graded modality*.

Having a family of modalities  $(!_m)_{m \in \mathbb{M}}$  with an arbitrary number of elements instead of the single  $!$  modality of original linear logic means that we cannot really have a distinct context for each of them as in the dyadic presentation. One solution is to go back to the monadic presentation, where variables carry their modality on their type until the very end when they get used. We would also need a new operator to go from  $!_m T$  to a pair  $!_{m-1} T, T$  so that we can extract a single use from a value wrapped in a modality allowing several uses. Actually, it gets hairy and unpractical very fast.

Fortunately, there's a way out of this. Instead of having  $m$  be part of the modality and thus of the type of terms, we can bake it in as an annotation on variable bindings. In place of  $x : S, y : !_m T, z : !_n U \vdash \dots$ , we can have  $x :_1 S, y :_m T, z :_n U \vdash$ . We'll call the new annotations on bindings *modes*. Note that every binding will be equipped with a mode  $m$ , even linear bindings that previously didn't have modalities on their types<sup>4</sup>. In addition to adding *modes* to bindings, we will also define a few algebraic operations on modes (and later by extension on bindings and typing contexts) that aim to encode the (sub)structural rules of our system, in a simpler and more extensive manner, without needing explicit syntax for them like **derelict** or **dup** anymore.

With the modal approach, we recover a system, like the dyadic one, in which contraction, weakening, and dereliction can be made conveniently implicit, without loosing any control power over resource use, and with no explosion of the number of contexts!

---

<sup>4</sup>This uniform approach where every binding receives a mode seems to originate in [Ghica and Smith, 2014] and [Petricek, Orchard, and Mycroft, 2014].

#### 1.4. Back to a single context with the graded modal approach

Furthermore, we build on the key insight —originally proposed in [Ghica and Smith, 2014]— that equipping the set of modes with a semiring structure is sufficient to express, algebraically, all the typing context manipulations we need. The idea is to define two main operations on modes: *multiplication*  $\cdot$ , which models how modes are compounded across nested expressions or function calls (for example, if a function  $f$  uses its argument with mode  $2$ , and  $g$  also uses its argument with mode  $2$ , then  $f(g\ x)$  uses  $x$  with mode  $2 \cdot 2$ ); and *addition*  $+$ , which accounts for what happens when a variable is used across multiple branches (for example, if subterm  $t$  uses  $x$  with mode  $2$  and  $u$  uses  $x$  with mode  $3$ , then  $t \ ; \ u$  uses  $x$  with mode  $2 + 3$ ). By abstracting away the structural restrictions of the type system as a mode system with a semiring structure, we make the type system much more scalable: if we were to enrich the type system, and if we are able to express the extension as a new semiring, then we almost don't have to modify the typing rules; just the underlying mode semiring.

We then lift the mode operators to variable bindings and typing contexts in the following way:

$$\begin{aligned}
n \cdot \cdot &\triangleq \cdot \\
n \cdot (x :_{\mathfrak{m}} \mathbb{T}, \Gamma) &\triangleq (x :_{n \cdot \mathfrak{m}} \mathbb{T}), n \cdot \Gamma \\
\cdot + \Gamma &\triangleq \Gamma \\
(x :_{\mathfrak{m}} \mathbb{T}, \Gamma_1) + \Gamma_2 &\triangleq x :_{\mathfrak{m}} \mathbb{T}, (\Gamma_1 + \Gamma_2) \quad \text{if } x \notin \Gamma_2 \\
(x :_{\mathfrak{m}} \mathbb{T}, \Gamma_1) + (x :_{\mathfrak{m}'} \mathbb{T}, \Gamma_2) &\triangleq x :_{\mathfrak{m} + \mathfrak{m}'} \mathbb{T}, (\Gamma_1 + \Gamma_2)
\end{aligned}$$

We'll now present the concrete *modal* formulation of the intuitionistic  $\lambda$ -calculus, which we denote  $\lambda_{Lm}$ . In fact, we do not use a full semiring here, since we do not require a zero element to encode linearity as we did in  $\lambda_{L1}$  and  $\lambda_{L2}$ . Instead, we work with a *semiring without zero* to represent modes —henceforth referred to as a *ringoid*— which still retains all the algebraic benefits described in [Ghica and Smith, 2014]. Our particular ringoid consists of only two elements:  $1$ , representing variables that must be managed linearly, and  $\omega$ , representing unrestricted variables. We give the following operation tables:

$+$	$1$	$\omega$
$1$	$\omega$	$\omega$
$\omega$	$\omega$	$\omega$

$\cdot$	$1$	$\omega$
$1$	$1$	$\omega$
$\omega$	$\omega$	$\omega$

Now that we have a completely defined the ringoid for modes, we can move to the grammar and typing rules of  $\lambda_{Lm}$ , given in Figures 1.6 and 1.7. The main change compared to  $\lambda_{L2}$  is that the constructor for  $!_{\mathfrak{m}} \mathbb{T}$  is now  $\text{Mod}_{\mathfrak{m}} t$  (instead of  $\text{Many } t$  for  $!\mathbb{T}$ ).

In  $\lambda_{Lm}$  we're back to a single identity rule  $\lambda_{Lm}\text{-TY/ID}$ , that asks for  $x$  to be in the typing context with a mode  $\mathfrak{m}$  that must be *compatible with a single linear use* (we note  $1 \preceq \mathfrak{m}$ ). In our ringoid, with only two elements, we have both  $1 \preceq 1$  and  $1 \preceq \omega$ , so  $x$  can actually have any mode (either linear or unrestricted, so encompassing both  $\lambda_{L2}\text{-TY/ID}_{\text{LIN}}$  and  $\lambda_{L2}\text{-TY/ID}_{\text{UR}}$ ), but in more complex modal systems, not all modes have to be compatible with the unit of the ringoid<sup>5</sup>. Rules  $\lambda_{Lm}\text{-TY/ID}$  and  $\lambda_{Lm}\text{-TY/!I}$  also allow to discard any context composed only of unrestricted bindings, denoted by  $\omega \cdot \Gamma$  (equivalent to notation  $!\Gamma$  in  $\lambda_{L1}$ ), so they are performing implicit weakening as in  $\lambda_{L2}$ .

Every rule of  $\lambda_{Lm}$  that mentions two subterms uses the newly defined  $+$  operator on typing contexts in the conclusion of the rule. If a same variable  $x$  is required in both  $\Gamma_1$  and  $\Gamma_2$  (either with mode  $1$  or  $\omega$ ), then  $\Gamma_1 + \Gamma_2$  will contain binding  $x :_{\omega} \mathbb{T}$ . Said differently, the superterm will

<sup>5</sup>See Section 2.5.2 for a case of a ringoid where not all modes are compatible with the unit.

$v ::= \lambda x_{\mathfrak{m}} \mapsto u \mid () \mid \text{Inl } v \mid \text{Inr } v \mid (v_1, v_2) \mid \text{Mod}_{\mathfrak{n}} v$   
 $t, u ::= v \mid x \mid \text{Inl } t \mid \text{Inr } t \mid (t_1, t_2) \mid \text{Mod}_{\mathfrak{n}} t \mid t \, t' \mid t \, ; \, t'$

 \end{array}$$

Figure 1.7: Typing rules for linear  $\lambda$ -calculus in modal presentation ( $\lambda_{Lm}\text{-TY}$ )

#### 1.4. Back to a single context with the graded modal approach

automatically deduce whether  $x$  needs to be linear or unrestricted based on how (many) subterms use  $x$ , thanks to the  $+$  operator. It's a vastly different approach than the linear context split for subterms in  $\lambda_{L1,2}$  and unrestricted context duplication for subterms in  $\lambda_{L2}$ . We would argue that, thanks to the algebraic properties of the mode semiring, it makes the presentation of the system smoother (at the theoretical level at least; implementing type checking for such a linear type system can be trickier).

Much as in  $\lambda_{L2}$ , the exponential modality  $!$  is eliminated by a **case**  $t$  of  $\text{Mod}_m x \mapsto u$  expression, that binds the scrutinee to a new variable  $x$  with mode  $m$ . The original boxed value can be recreated if needed with  $\text{Mod}_m x$ ; indeed, as in  $\lambda_{L2}$ , elimination rule for  $!$  is *not* dereliction.

The last specificity of this system is that the function arrow  $\multimap$  now carries a mode  $m$  to which it binds its argument. Previously, in  $\lambda_{L1,2}$ , the argument of a function was always linear, meaning that the corresponding variable binding in the function body was linear. Here, in  $\lambda_{Lm}$ , we can bind the argument at any mode  $m$ —and the rule  $\lambda_{Lm}\text{-TY}/\multimap\text{E}$  for function application reflects this: the typing context  $\Gamma_1$  for the argument passed to the function is multiplied by  $m$  in the conclusion of the rule. Actually, this does not change the expressivity of the system compared to previous presentations. For instance, the function  $\lambda x. m \mapsto u : T_m \multimap U$  can be encoded as  $\lambda x'. \text{case } x' \text{ of } \text{Mod}_m x \mapsto u : !_m T \multimap U$  using just the purely linear function arrow (at call site, we simply wrap the argument explicitly in an exponential, i.e., replacing  $f x$  by  $f' (\text{Mod}_m x)$ ). But since every variable binding must be assigned a mode in this presentation anyway, it is natural to allow this mode  $m$  to be whatever the programmer chooses—not just defaulting to  $1$ —thereby reducing the noise of explicit wrapping and unwrapping from modalities.

Let's update our running example. The term syntax doesn't change, we only see an evolution in typing contexts (as we now have only one, with mode annotations, instead of two):

$$\frac{\frac{\frac{1 \leq 1}{y : \omega U, x : !_1 T \vdash x : ! T} \text{ID} \quad \frac{\frac{1 \leq 1}{y : \omega U, x' : !_1 T \vdash x' : T} \text{ID} \quad \frac{1 \leq 1}{y : \omega U, x' : !_1 T \vdash x' : T} \text{ID}}{y : \omega U, x' : \omega T \vdash (x', x') : T \otimes T} \otimes \text{I}}{y : \omega U, x : !_1 T \vdash \text{case } x \text{ of } \text{Mod}_\omega x' \mapsto (x', x') : T \otimes T} !\text{E}}{y : \omega U \vdash \lambda x. 1 \mapsto \text{case } x \text{ of } \text{Mod}_\omega x' \mapsto (x', x') : !_1 T \multimap T \otimes T} \multimap \text{I}$$

In  $\lambda_{Lm}$ , we are only forced to carry the unrestricted, unused part of the typing context ( $y : \omega U$  in this case) towards at least one of the leaves, not all of them, thanks to the way the  $+$  works on contexts. For instance, the following is equally valid:

$$\frac{\frac{\frac{1 \leq 1}{y : \omega U, x : !_1 T \vdash x : ! T} \text{ID} \quad \frac{\frac{1 \leq 1}{x' : !_1 T \vdash x' : T} \text{ID} \quad \frac{1 \leq 1}{x' : !_1 T \vdash x' : T} \text{ID}}{x' : \omega T \vdash (x', x') : T \otimes T} \otimes \text{I}}{y : \omega U, x : !_1 T \vdash \text{case } x \text{ of } \text{Mod}_\omega x' \mapsto (x', x') : T \otimes T} !\text{E}}{y : \omega U \vdash \lambda x. 1 \mapsto \text{case } x \text{ of } \text{Mod}_\omega x' \mapsto (x', x') : !_1 T \multimap T \otimes T} \multimap \text{I}$$

We also could have chosen to type  $x'$  at mode  $\omega$  in the two identical instances of the  $\lambda_{Lm}\text{-TY}/\text{ID}$  rule at the top of the tree; it has no impact on the rest of the derivation as both  $1 + 1$  and  $\omega + \omega$  gives  $\omega$  as a result. The fact that we now have a few choices to make when typing a term in  $\lambda_{L1}\text{-TY}$ —which we did not have in  $\lambda_{L2}\text{-TY}$ —is the only non-trivial aspect when attempting to show that the two systems are equivalent.

Finally, we can give an alternative and more concise version of this function, taking advantage of the *mode on function arrow* feature that we just discussed above. This new version has type  $\mathsf{T} \multimap \mathsf{T} \otimes \mathsf{T}$  instead of  $!\mathsf{T} \multimap \mathsf{T} \otimes \mathsf{T}$ :

$$\frac{\frac{\frac{1 \leq 1}{y : \omega \mathsf{U}, x' : \mathsf{T} \vdash x' : \mathsf{T}} \text{ID}}{\frac{y : \omega \mathsf{U}, x' : \omega \mathsf{T} \vdash (x', x') : \mathsf{T} \otimes \mathsf{T}}{\mathsf{T} \otimes \mathsf{T}} \otimes \text{I}} \multimap \text{I}}{\frac{y : \omega \mathsf{U} \vdash \lambda x' \multimap (x', x') : \mathsf{T} \multimap \mathsf{T} \otimes \mathsf{T}}{\mathsf{T} \multimap \mathsf{T} \otimes \mathsf{T}} \multimap \text{I}}$$

## 1.5 Deep modes: projecting modes through fields of data structures

In original linear logic from Girard (see ILL and presentation  $\lambda_{L1}$  above), there is only a one-way morphism between  $!\mathsf{T} \otimes \mathsf{U}$  and  $!(\mathsf{T} \otimes \mathsf{U})$ ; we cannot go from  $!(\mathsf{T} \otimes \mathsf{U})$  to  $!\mathsf{T} \otimes \mathsf{U}$ . In other terms, an unrestricted pair  $!(\mathsf{T} \otimes \mathsf{U})$  doesn't allow for unrestricted use of its components. The pair can be duplicated or discarded at will, but to be used, it needs to be derelicted first, to become  $\mathsf{T} \otimes \mathsf{U}$ , that no longer allow to duplicate or discard any of  $\mathsf{T}$  or  $\mathsf{U}$ . As a result,  $\mathsf{T}$  and  $\mathsf{U}$  will have to be used exactly the same number of times, even though they are part of an unrestricted pair!

Situation is no different in  $\lambda_{L2}$  (resp.  $\lambda_{Lm}$ ): although the pair of type  $!(\mathsf{T} \otimes \mathsf{U})$  can be bound in an unrestricted binding  $x : \mathsf{T} \otimes \mathsf{U} \in \mathcal{U}$  (resp.  $x : \omega \mathsf{T} \otimes \mathsf{U}$  in  $\lambda_{Lm}$ ) and be used as this without need for dereliction, when it will be pattern-matched on (through the rule  $\lambda_{L2,m}\text{-TY}/\otimes \text{E}$ ), implicit dereliction will still happen, and linear-only bindings will be made for its components:  $x_1 : \mathsf{T}$ ,  $x_2 : \mathsf{U}$  in the linear typing context (resp.  $x_1 : \mathsf{T}$ ,  $x_2 : \mathsf{U}$  in  $\lambda_{Lm}$ ).

Let's say we want to write the **fst** function, that extracts the first element of a pair. In a non-linear language, we would probably write it that way:

```
fstnl :  $\mathsf{T} \otimes \mathsf{U} \rightarrow \mathsf{T}$ 
fstnl  $\triangleq$  case  $\lambda x \mapsto x$  of  $(x_1, x_2) \mapsto x_1$ 
```

But in  $\lambda_{Lm}$ , or even  $\lambda_{L1,2}$ , we are not allowed to do this. A naive idea would be to give the function the signature  $\mathsf{T} \otimes \mathsf{U} \multimap \mathsf{T}$ , but that still doesn't help: as we just said, even with an unrestricted pair, we have to consume both elements of the pair the same number of times. The only valid solution is to indicate, in the signature, that the second element of the pair—that we discard—will not be used linearly, by wrapping it in a  $!\omega$  modality:

```
fstm :  $\mathsf{T} \otimes (!\omega \mathsf{U}) \multimap \mathsf{T}$ 
fstm  $\triangleq$  case  $\lambda x \mapsto x$  of  $(x_1, ux_2) \mapsto$ 
    case  $ux_2$  of Mod $\omega$   $x_2 \mapsto x_1$ 
```

In a real programming context, where linearity is not always the main concern, it gets quite tiresome to have to insert  $!\omega$  modalities everywhere in the types, and **case**  $t$  of Mod <sub>$m$</sub>   $x \mapsto \dots$  everywhere in the terms. Ideally we would like programs valid in the usual  $\lambda$ -calculus to have a valid interpretation in our linear  $\lambda$ -calculus with almost no change required, especially to the syntax.

### 1.5. Deep modes: projecting modes through fields of data structures

We can do that with *deep modes*. Deep modes is a common feature in practical modal languages, that consists in allowing modes or their corresponding graded modalities to commute with other data types such as sums and products. It has, for instance, been implemented in Linear Haskell [Bernardy et al., 2018], Granule [Orchard, Liepelt, and Eades III, 2019], and the more recent Modal OCaml [Lorenzen, White, et al., 2024].

With deep modes, we obtain the following equivalences:

$$\begin{aligned} !_{\mathfrak{m}}(\mathbf{T} \otimes \mathbf{U}) &\simeq (!_{\mathfrak{m}} \mathbf{T}) \otimes (!_{\mathfrak{m}} \mathbf{U}) \\ !_{\mathfrak{m}}(\mathbf{T} \oplus \mathbf{U}) &\simeq (!_{\mathfrak{m}} \mathbf{T}) \oplus (!_{\mathfrak{m}} \mathbf{U}) \\ !_{\mathfrak{m}}(!_{\mathfrak{n}} \mathbf{T}) &\simeq !_{(\mathfrak{m} \cdot \mathfrak{n})} \mathbf{T} \end{aligned}$$

In our modal linear  $\lambda$ -calculus extended with deep modes (further denoted  $\lambda_{Ldm}$ ), functions of type  $\mathbf{T} \multimap_{\omega} \mathbf{U}$  can represent all the ones having type  $\mathbf{T} \rightarrow \mathbf{U}$  in STLC. If we conveniently use compatible syntax for terms and types in both systems, then there is almost no change required to go from a function valid in STLC to one valid in  $\lambda_{Ldm}$ ; we just need to add a few modes annotations (both in terms and types). This contrasts with a faithful interpretation of Girard's linear logic, like we just showed before with  $\lambda_{Lm}$ , where we need to introduce (and then destruct) modalities explicitly whenever a non-linear control flow occurs (as in **fst**<sub>m</sub>).

Revisiting this **fst** function, with deep modes in  $\lambda_{Ldm}$ , we are able to write:

$$\begin{aligned} \mathbf{fst}_{dm} &: \mathbf{T} \otimes \mathbf{U} \multimap_{\omega} \mathbf{T} \\ \mathbf{fst}_{dm} &\triangleq \mathbf{case}_{\omega} \lambda x \multimap_{\omega} x \text{ of } (x_1, x_2) \mapsto x_1 \end{aligned}$$

This is precisely the same implementation as **fst**<sub>nl</sub>, with just extra mode annotations!

**Formal changes in the grammar and typing rules for deep modes** The only change needed on the grammar between  $\lambda_{Lm}$  and  $\lambda_{Ldm}$  is that the **case** constructs in  $\lambda_{Ldm}$  take a mode  $\mathfrak{m}$  to which they consume the scrutinee, which is propagated to the variable bindings for the field(s) of the scrutinee in the body of the **case**. The new typing rules for **case** are presented in Figure 1.8, all the other rules of linear  $\lambda$ -calculus with deep modes,  $\lambda_{Ldm}$ , are identical to those of Figure 1.7.

For these new **case** rules, we observe that the typing context  $\Gamma_1$  in which the scrutinee types is scaled by  $\mathfrak{m}$  in the conclusion of these rules. This is very similar to the application rule  $\lambda_{Lm}\text{-TY}/\multimap\text{E}$ : it makes sure that the resources required to type  $t$  are consumed  $\mathfrak{m}$  times if we want to use  $t$  at mode  $\mathfrak{m}$ . Given that  $x_2 : !_{\mathfrak{1}} \mathbf{T}_2 \vdash (( ), x_2) : !_{\mathfrak{1}} \otimes \mathbf{T}_2$  (the pair uses  $x_2$  exactly once), if we want to extract the pair components with mode  $\omega$  to drop  $x_2$  (as in **fst**<sub>dm</sub>), then **case** <sub>$\omega$</sub>   $(( ), x_2)$  **of**  $(x_1, x_2) \mapsto x_2$  will require context  $\omega \cdot (x_2 : !_{\mathfrak{1}} \mathbf{T}_2)$  i.e.  $x_2 : \omega \mathbf{T}_2$ . In other terms, we cannot use parts of a structure having dependencies on linear variables in an unrestricted way (as that would break linearity).

The linear  $\lambda$ -calculus with deep modes,  $\lambda_{Ldm}$ , will be the basis for our core contribution that follows in next chapter: the destination calculus  $\lambda_d$ .

$\boxed{\Gamma \vdash t : \mathbb{T}}$

 \end{array}$$

 Figure 1.8: Altered typing rules for deep modes in linear  $\lambda$ -calculus in modal presentation ( $\lambda_{Ldm}^{\text{TY}}$ )

## 1.6 Operational semantics of linear $\lambda$ -calculus (with deep modes)

Many semantics presentations exist for the  $\lambda$ -calculus. In Figure 1.9 we present a small-step reduction system for  $\lambda_{Ldm}$ , in *reduction semantics* style inspired from [Felleisen, 1987] and subsequent [Danvy and Nielsen, 2004; Biernacka and Danvy, 2007], that is, a semantics in which the evaluation context  $E$  is manipulated explicitly and syntactically as a stack.

We represent a running program by a pair  $E[t]$  of an evaluation context  $E$ , and a term  $t$  under focus. We call such a pair  $E[t]$  a *command*, borrowing the terminology from Curien and Herbelin [2000].

Small-step evaluation rules are of three kinds:

- focusing rules (F) that split the current term under focus in two parts: an evaluation context component that is pushed on the stack  $E$  for later use, and a subterm that is put under focus;
- unfocusing rules (U) that recreate a larger term once the term under focus is a value, by popping the most recent evaluation component from the stack and merging it with the value;
- contraction rules (C) that do not operate on the stack  $E$  but just transform the term under focus when it's a redex (following a terminology introduced in [Danvy and Nielsen, 2004; Biernacka and Danvy, 2007]).

To have a fully deterministic and straightforward reduction system, focusing rules can only trigger when the subterm that would be focused is not already a value (denoted by  $\star$  in Figure 1.9).

Data constructors only have focusing and unfocusing rules, as they do not describe computations that can be reduced. In that regard,  $\text{Mod}_{\mathfrak{m}} t$  is treated as an unary data constructor. Once a data constructor is focused, it is evaluated fully to a value form.

In most cases, unfocusing and contraction rules could be merged into a single step. For example, a contraction could be triggered as soon as we have  $(E \circ \text{case}_{\mathfrak{m}} [] \text{ of } (x_1, x_2) \mapsto u) [(v_1, v_2)]$ , without the need to recreate the term  $\text{case}_{\mathfrak{m}}(v_1, v_2) \text{ of } (x_1, x_2) \mapsto u$ . However, we prefer the presentation in three distinct steps, that despite being more verbose, clearly shows that contraction rules do not modify the evaluation context.

### 1.6. Operational semantics of linear $\lambda$ -calculus (with deep modes)

$\boxed{E[t] \longrightarrow E'[t']}$	(Small-step evaluation)
$E[\text{Inl } t] \longrightarrow (E \circ \text{Inl } []) [t]$	$\star \oplus_1 F$
$(E \circ \text{Inl } []) [v] \longrightarrow E[\text{Inl } v]$	$\oplus_1 U$
$E[\text{Inr } t] \longrightarrow (E \circ \text{Inr } []) [t]$	$\star \oplus_2 F$
$(E \circ \text{Inr } []) [v] \longrightarrow E[\text{Inr } v]$	$\oplus_2 U$
$E[(t_1, t_2)] \longrightarrow (E \circ ([], t_2)) [t_1]$	$\star \otimes IF_1$
$(E \circ ([], t_2)) [v_1] \longrightarrow E[(v_1, t_2)]$	$\otimes IU_1$
$E[(v_1, t_2)] \longrightarrow (E \circ (v_1, [])) [t_2]$	$\star \otimes IF_2$
$(E \circ (v_1, [])) [v_2] \longrightarrow E[(v_1, v_2)]$	$\otimes IU_2$
$E[\text{Mod}_n t] \longrightarrow (E \circ \text{Mod}_n []) [t]$	$\star !IF$
$(E \circ \text{Mod}_n []) [v] \longrightarrow E[\text{Mod}_n v]$	$!IU$
$E[t' t] \longrightarrow (E \circ t' []) [t]$	$\star \multimap EF_1$
$(E \circ t' []) [v] \longrightarrow E[t' v]$	$\multimap EU_1$
$E[t' v] \longrightarrow (E \circ [] v) [t']$	$\star \multimap EF_2$
$(E \circ [] v) [v'] \longrightarrow E[v' v]$	$\multimap EU_2$
$E[(\lambda x_{\text{m}} \mapsto u) v] \longrightarrow E[u[x := v]]$	$\multimap EC$
$E[t \mathbin{\text{\textcircled{;}}} u] \longrightarrow (E \circ [] \mathbin{\text{\textcircled{;}}} u) [t]$	$\star 1EF$
$(E \circ [] \mathbin{\text{\textcircled{;}}} u) [v] \longrightarrow E[v \mathbin{\text{\textcircled{;}}} u]$	$1EU$
$E[() \mathbin{\text{\textcircled{;}}} u] \longrightarrow E[u]$	$1EC$
$E[\text{case}_n t \text{ of } \{\text{Inl } x_1 \mapsto u_1, \text{Inr } x_2 \mapsto u_2\}] \longrightarrow (E \circ \text{case}_m [] \text{ of } \{\text{Inl } x_1 \mapsto u_1, \text{Inr } x_2 \mapsto u_2\}) [t]$	$\star \oplus EF$
$(E \circ \text{case}_m [] \text{ of } \{\text{Inl } x_1 \mapsto u_1, \text{Inr } x_2 \mapsto u_2\}) [v] \longrightarrow E[\text{case}_n v \text{ of } \{\text{Inl } x_1 \mapsto u_1, \text{Inr } x_2 \mapsto u_2\}]$	$\oplus EU$
$E[\text{case}_n (\text{Inl } v_1) \text{ of } \{\text{Inl } x_1 \mapsto u_1, \text{Inr } x_2 \mapsto u_2\}] \longrightarrow E[u_1[x_1 := v_1]]$	$\oplus EC_1$
$E[\text{case}_n (\text{Inr } v_2) \text{ of } \{\text{Inl } x_1 \mapsto u_1, \text{Inr } x_2 \mapsto u_2\}] \longrightarrow E[u_2[x_2 := v_2]]$	$\oplus EC_2$
$E[\text{case}_n t \text{ of } (x_1, x_2) \mapsto u] \longrightarrow (E \circ \text{case}_m [] \text{ of } (x_1, x_2) \mapsto u) [t]$	$\star \otimes EF$
$(E \circ \text{case}_m [] \text{ of } (x_1, x_2) \mapsto u) [v] \longrightarrow E[\text{case}_n v \text{ of } (x_1, x_2) \mapsto u]$	$\otimes EU$
$E[\text{case}_n (v_1, v_2) \text{ of } (x_1, x_2) \mapsto u] \longrightarrow E[u[x_1 := v_1][x_2 := v_2]]$	$\otimes EC$
$E[\text{case}_n t \text{ of } \text{Mod}_n x \mapsto u] \longrightarrow (E \circ \text{case}_m [] \text{ of } \text{Mod}_n x \mapsto u) [t]$	$\star !EF$
$(E \circ \text{case}_m [] \text{ of } \text{Mod}_n x \mapsto u) [v] \longrightarrow E[\text{case}_n v \text{ of } \text{Mod}_n x \mapsto u]$	$!EU$
$E[\text{case}_n \text{Mod}_n v \text{ of } \text{Mod}_n x \mapsto u] \longrightarrow E[u[x := v]]$	$!EC$

$\star$  : only allowed if the term that would become the new focus is not already a value

Figure 1.9: Small-step semantics for  $\lambda_{Ldm}$  ( $\lambda_{Ldm}$ -sem)

The rest of the system is very standard. In particular, contraction rules of  $\lambda_{Ldm}$  —that capture the essence of the calculus— are very similar to those of lambda-calculi with sum and product types (and strict evaluation strategy).

For instance, let's see the reduction for function application. We reuse the same example of our function with signature  $!T \multimap (T \otimes T)$ , here applied to the argument  $\text{Mod}_\omega(\text{Inl } ())$ :

$$\begin{aligned}
 & [][(\lambda x. \text{case } x \text{ of } \text{Mod}_\omega x' \mapsto (x', x')) (\text{Mod}_\omega(\text{Inl } ()))] \\
 \longrightarrow & [][(\text{case } \text{Mod}_\omega(\text{Inl } ()) \text{ of } \text{Mod}_\omega x' \mapsto (x', x'))] & \multimap\text{EC} \quad \text{with substitution } x := \text{Mod}_\omega(\text{Inl } ()) \\
 \longrightarrow & [][(\text{Inl } (), \text{Inl } ())] & !\text{EC} \quad \text{with substitution } x' := \text{Inl } ()
 \end{aligned}$$

Because we have a function in value form already, with simple body, applied to a value, we don't need to focus into a subterm and unfocus back later; we see only see a succession of contraction steps.

A command of the form  $[] [v]$  with  $v$  a value is the stopping point of the reduction for all well-typed programs. If we have a non-value term  $t$  in  $[] [t]$  then a focusing or contraction step should trigger; and if we have a non-empty evaluation context  $E$  in  $E[v]$  then an unfocusing step should trigger. Only ill-shaped term or value can cause the reduction to be stuck, which is a symptom of a wrongly-typed program.

## 1.7 Linear Types in Haskell

As part of this PhD work, we intend to implement prototypes in an industrial functional programming language as we explore the destination-passing world. Haskell is a suitable target for that, thanks to its support for linear types. In what follows, we give the reader a quick overview of Linear Haskell and how the concepts discussed above map into the Haskell world..

Linear Haskell [Bernardy et al., 2018] is a language extension for the Glasgow Haskell Compiler (GHC) that introduces the linear function arrow,  $t \multimap u$  and modifies the type checker of GHC so that it can enforce linearity requirements. A linear function of type  $t \multimap u$  guarantees that the argument of the function will be consumed exactly once when the result of the function is consumed exactly once. The regular function arrow  $t \rightarrow u$  is still available when Linear Haskell is enabled; this one doesn't guarantee how many times its argument will be consumed when its result is consumed once. Actually Linear Haskell is based on a modal formalism, like  $\lambda_{Ldm}$ , so there is also a multiplicity-polymorphic arrow,  $t \%m \rightarrow u$ , much like  $T_m \multimap U$ ; so  $t \multimap u$  and  $t \rightarrow u$  are sugar for  $t \%1 \rightarrow u$  and  $t \% \omega \rightarrow u$  respectively.

A value is said to be *consumed once* (or *consumed linearly*) when it is pattern-matched on and its sub-components are consumed once; or when it is passed as an argument to a linear function whose result is consumed once. A function is said to be *consumed once* when it is applied to an argument and when the result is consumed exactly once. We say that a variable  $x$  is *used linearly* in an expression  $u$  when consuming  $u$  once implies consuming  $x$  exactly once. This is no more than a practical view of the typing rules given for  $\lambda_{Ldm}$ .

**Unrestricted Values** Linear Haskell introduces a wrapper named `Ur` which is used to indicate that a value in a linear context doesn't have to be used linearly. `Ur t` is the Haskell equivalent for  $!T$  in  $\lambda_{L1,2}$  or  $!_{\omega}T$  in  $\lambda_{Ldm}$ , and there is an equivalence between `Ur t  $\multimap$  u` and `t  $\rightarrow$  u`. As in  $\lambda_{L2}$  and  $\lambda_{Ldm}$ , we can pattern-match on a term of type `Ur t` with `case term of Ur x  $\multimap$  term'` to obtain an unrestricted variable binding `x` of type `t`.

As usual with linear type systems, only values already wrapped in `Ur` or coming from the left of a non-linear arrow can be put in another `Ur` without breaking linearity. This echoes rules  $\lambda_{L1-TY}/!P$  or  $\lambda_{L2,m-TY}/!I$  where a term wrapped in `Many` or `Mod $_{\omega}$`  must only depend on an unrestricted context. The only exceptions to this rule are terms of types that implement the `Movable` typeclass<sup>6</sup> such as `Int` or `()`. `Movable` provides the function `move :: t  $\multimap$  Ur t`, that is, unconditional promotion to `Ur` for types implementing this typeclass.

**Operators** Some Haskell operators and notations are often used in the rest of this article:

`(;) :: ()  $\multimap$  u  $\multimap$  u` is used to chain a linear operation returning `()` with one returning a value of type `u` without breaking linearity. It's the Haskell equivalent of  $\lambda_{Ldm-TY}/!E$ . It isn't part of the core Haskell syntax, but can be defined simply as `case term1 of () -> term2`.

`Class  $\Rightarrow$  ...` is notation for typeclass constraints (resolved implicitly by the compiler).

`@t in f @t ...` is a type application; it allows to specify an explicit type for polymorphic functions.

In code excerpts, types are in blue, while terms, variables, and data constructors (sometimes having the same name as the type they belong to, like `Ur` (type) / `Ur` (data constructor)) are in black, to stay as consistent as possible with previous chapters. Unfortunately, while type variables `T, U` are in uppercase in our formalism, we have no choice than to use lowercase letters in Haskell `t, u`.

## 1.8 Uniqueness and Linear Scopes

In the introduction, we said that we will use linear type systems to control the number of times a resource—in particular a destination—is used. A more usual approach to resource management in functional programming is to encapsulate resources within monads. While monads can ensure controlled access, they are contaminating: once a computation touches a monadic value, the surrounding code is typically forced to adopt the same monadic structure, even if it does not manipulate the resource directly. This tends to blur the boundaries between pure and effectful code, making programs harder to read, compose, and refactor. Linear type systems, by contrast, promise precise control over resource usage, without the pervasive overhead, as programs can stay in “direct style”.

But linear type systems, at first, may seem insufficient to do that job fully. In a linear type system, we can only promise what we do to a value we receive. We cannot say much about what has been done to it previously. And thus, we cannot ensure it has been used exactly once *overall*.

For instance, given a function of type `t  $\multimap$  u`, if we apply it to an argument of type `t`, we know we won't duplicate this value of type `t` (as long as we use the result of type `u` exactly once). But we can't say whether the `t` has been duplicated or not beforehand: that's a major issue.

<sup>6</sup>The `Movable` typeclass is not part of the Linear Haskell language extension, but instead defined in the linear-base library.

Stating facts about *the past* of a value is the land of *uniqueness typing* or unique type systems. In a unique type system, the main property is not how many times a function uses a value to produce its output, but rather, whether a value has been aliased or not. Uniqueness (or non-uniqueness) is a property on values, while linearity is a property on functions<sup>7</sup>. Having uniqueness or non-uniqueness property on values allows for easier control of resources that should always stay unique during their lifetime. The most common example is efficient implementation of functional arrays. If an array is handled uniquely and isn't shared, then we can implement array updates as in-place memory mutations [Marshall, Vollmer, and Orchard, 2022]. By being able to state uniqueness of values, statically through the type system, we can allow predictable compiler optimizations.

The thing is, uniqueness typing doesn't have a theoretical ground as rich as linear types. Unlike linearity, uniqueness properties have first been studied on the computational side and only later studied on the logical side, with [Harrington, 2006]. There are also two downsides of uniqueness typing for what we want to do later. First, there isn't an easy way with unique type system to force the use of something (and we definitely want a way to force a destination to be used and not just be dropped). We can state or prove that it isn't aliased, but that's all. Secondly, and more importantly perhaps, higher-order functions (capturing lambda abstractions) are way more finicky in unique type systems, as detailed in Section 5 of [Harrington, 2006] or mentioned briefly in [Marshall, Vollmer, and Orchard, 2022] (that's one reason why they prefer a linear system as a basis with a uniqueness topping instead of a uniqueness system with a linearity topping).

Actually, Marshall, Vollmer, and Orchard [2022] argue that modern programming languages would benefit from integrating both linear and uniqueness typing, as linearity and uniqueness appear to be half-dual, half-complementary notions that together are enough for a very precise control of resource usage in a language. More recently, in that sense, Lorenzen, White, et al. [2024] included both *affinity* (the resource must be used at most once) and uniqueness in their modal system, and studied their interactions with one another.

In Chapter 3 however, our main target language will be Haskell, which doesn't have uniqueness typing, only linear types, as detailed in Section 1.7. Fortunately, we can emulate uniqueness control in a language equipped with linear types, using *linear scopes* or the *scope function trick*, as one might call it.

**Linear scopes** As we said before, in Linear Haskell, as in most linear type systems, functions can be made to use their arguments linearly or not. In other terms, linearity is a contract that links the input and output of a function. But we cannot say anything a priori about what happened to the value passed as a parameter before the function call, or what happens to the function result after. Linearity control can only be enforced on *variables*.

Let say we want to design a file API without monads (that's actually one interesting use of linear/unique types). Assuming the following simplified API, one could write this small program:

---

<sup>7</sup>At least in the presentations above that follows from Girard's Linear Logic. There exists approaches of Linear Type systems that are more focused on the programming side, for which linearity is a property of values and their types, not functions.

```

1 | openFile :: String → File
2 | closeFile :: File → ()
3
4 | file :: File -- no way to force this value to be used exactly once
5 | file = openFile "test.txt"
6
7 | nonLinearUseButValid :: () =
8 |   closeFile file ; closeFile file -- valid even if file is consumed twice

```

With call-by-value or call-by-need semantics, the side-effects of `openFile` will be produced only once, while the side effects of `closeFile` will be produced twice, resulting in an error.

The solution to that is to forbid the consumer from creating and directly accessing a value of the resource type for which we want to enforce linearity/uniqueness. Instead, we force the consumer of a resource to pass a continuation representing what they want to do on the resource, so that we can check through its signature that it is indeed a linear continuation:

```

1 | withFile :: String → (File → t) → t
2 | closeFile :: File → ()
3 | nonLinearUseAndEffectivelyRejected :: () =
4 |   withFile "test.txt" (\file → closeFile file ; closeFile file) -- not linear

```

The `File` type is in positive position in the signature of `withFile`, so the function `withFile` should somehow know how to produce a `File`, but this is opaque for the user. What matters is that a file can only be accessed by providing a linear continuation to `withFile`.

Still, this is not enough; because `\file → file` is indeed a linear continuation, one could use `withFile "test.txt" (\file → file)` to leak a `File`, and then use it in a non-linear fashion in the outside world. Hence we must forbid `File` from appearing anywhere in the return type of the continuation.

To do that, we ask the return type to be wrapped in the unrestricted modality `Ur` (the equivalent in the Linear Haskell realm to the `!` modality): because the value of type `File` comes from the left of a linear arrow, it cannot be promoted to an `Ur` without breaking linearity, so it cannot leave the scope and has to be used exactly once in this scope. That's why we speak of *linear scopes*. Here's the updated example:

```

1 | withFile' :: String → (File → Ur t) → Ur t
2 | closeFile :: File → ()
3 | exampleOk :: Ur () = withFile' "test.txt" (\file → closeFile file ; Ur ())
4 | exampleFail :: Ur File =
5 |   withFile' "test.txt" (\file → Ur file) -- leaking file, effectively rejected

```

Still, this solution is not perfect. We effectively prevent any linear resource from leaving the scope, even resources that have nothing to do with the file API and have been created in outer scopes! This issue is talked in length by Spiwack [2023b]. It manifests itself in the following example, which gets rejected:

```

1  | readLine :: File -> (Ur String, File)
2  | writeLine :: File -> String -> File
3
4  | exampleFail' :: Ur () =
5  |   withFile' "test.txt" (\file1 ->
6  |     ...
7  |     withFile' "test2.txt" (\file2 ->
8  |       let (Ur line, file1') = readLine file1
9  |         file2' = writeLine file2 line
10 |         in closeFile file2' ; Ur file1')
11 |     ... -- other operations with file1' here
12 | )

```

The problem here is that we cannot return `file1'` from the inner scope, because it's a linear resource that cannot be promoted to `Ur`. However, it would be perfectly safe to do so; it's just that we don't have precise enough tools at type level to convince the compiler of this fact.

In that case, the most obvious workaround is to extend the scope of `withFile' "test2.txt" (file2 -> ...)` as long as we need to operate on `file1'`. Very unfortunate and unpractical indeed to have to prolongate the inner scope because we still need to operate on resources from the outer one!<sup>8</sup>

One easy improvement we can do is to have a single linear scope, providing a linear token type, and let this token type be used to instantiate any resource for which we want to enforce linearity/uniqueness. That way, we can just have one big linear scope, and write most of the code in direct style, still without monads!

```

1  | type Token
2  | dup :: Token -> (Token, Token)
3  | drop :: Token -> ()
4  | withToken :: (Token -> Ur t) -> Ur t
5
6  | -- A first linear API
7  | openFile' :: String -> Token -> File
8  | closeFile :: File -> ()
9
10 | -- A second linear API
11 | openDB :: String -> String -> Token -> DB
12 | closeDB :: DB -> ()
13
14 | exampleOk1 :: Ur () =
15 |   withToken (\tok -> let file = openFile' "test.txt" tok in closeFile file ; Ur ())
16 | exampleOk2 :: Ur () =
17 |   withToken (\tok -> let (tok1, tok2) = dup tok
18 |                       file = openFile' "test.txt" tok1
19 |                       db = openDB "localhost" 3306 tok2
20 |                       in closeFile file ; closeDB db ; Ur ())
21 | exampleRejected :: Ur File =
22 |   withToken (\tok -> Ur (openFile' "test.txt" tok)) -- leaking file which linearly depends on tok

```

<sup>8</sup>This is what is referred to as *sticky end of linear scopes* in [Spiwack, 2023b]

What might be surprising here is that we are allowed to duplicate or drop a token (with `dup` or `drop`), which we announced as a linear resource!

In fact, the goal of the `Token` type is to tie every resource to a linearity requirement. The important part is that the `Token` type should not have a way to be promoted to `Ur`, otherwise tokens and other linear resources could leak and live outside of the linear scope of `withToken`.

The linear `dup` function creates two tokens out of one, but still tie the resulting tokens to the input one through a linear arrow. Allowing to duplicate tokens doesn't allow the consumer to duplicate the resources we want to control (files, database handles, etc.). So we're safe on that front.

With this approach, dealing with multiple linear resource types is much more uniform. We can use any remaining token to instantiate one or several new linear resources. As we only have one big linear scope, with every linear resource in it, there is no issue with nested scopes that need to be extended. When a program is sliced into many sub-functions, these functions don't even have to deal or know about the linear scope; they just have to pass around and receive tokens, and can otherwise be written in direct style.

Although it's out of scope for this document, Spiwack et al. [2022] goes further on the idea of linear tokens and scopes, with *Linear constraints*, which are roughly a way to pass tokens around in an implicit fashion, to make programming with linear types even more convenient<sup>9</sup>.

In next chapters, we will reuse the *linear scope with tokens* strategy to enforce linearity and uniqueness on linear resources, to allow safe effects in pure, direct-style APIs.

## 1.9 Conclusion

In this chapter we introduced the linear  $\lambda$ -calculus, from its roots in linear logic, to more practical and computation-centric presentations. In particular, we laid theoretical foundations for a modal linear  $\lambda$ -calculus, which will be reused in the rest of this document.

Furthermore, we explored Linear Haskell, as a concrete target for experimenting with linear types. In particular, we illustrated how linear types can help with managing unique resources, that must be used but also must not be duplicated, even though it requires a bit of care to avoid the inherent limitations of linear types (in that, they can't guarantee per se what happened to a value in the past).

We are now in comfortable ground and have all the tool needed to explore both theoretical and practical aspect of functional destination passing.

---

<sup>9</sup>At the time of writing this document, Linear Constraints are seriously considered to be added into GHC, the main Haskell compiler [Spiwack, 2023a].

## Chapter 2

# A formal functional language based on first-class destinations: $\lambda_d$

In the previous chapter we laid out important building blocks for the functional language that we develop here, namely  $\lambda_d$ . Let’s see why destination passing is valuable in a pure functional programming context, and how  $\lambda_d$  constitutes a good foundational layer for this.

The results presented in this chapter have also been published at the OOPSLA 2025 conference [Bagrel and Spiwack, 2025].

### 2.1 Destination-passing style programming, in a functional setting

In destination-passing style, a function doesn’t return a value: it takes as an argument a location —named *destination*— where the output of the function ought to be written. In this chapter, we will denote destinations by  $\llbracket \mathbf{T} \rrbracket$  where  $\mathbf{T}$  is the type of what can be stored in the destination. A function of type  $\mathbf{T} \rightarrow \mathbf{U}$  would have signature  $\mathbf{T} \rightarrow \llbracket \mathbf{U} \rrbracket \rightarrow \mathbf{1}$  when transformed into destination-passing style. Instead of returning an  $\mathbf{U}$ , it consumes a destination of type  $\llbracket \mathbf{U} \rrbracket$  and returns just *unit* (type  $\mathbf{1}$ ). This style is common in systems programming, where destinations  $\llbracket \mathbf{U} \rrbracket$  are more commonly known as *out parameters* (in C,  $\llbracket \mathbf{U} \rrbracket$  would typically be a pointer of type  $\mathbf{U}^*$ ).

The reason why systems programs rely on destinations so much is that using destinations can save calls to the memory allocator, which are costly, in a context where every gain of performance is highly valuable. If a function returns a  $\mathbf{U}$ , it has to allocate the space for a  $\mathbf{U}$ . But with destinations, the caller is responsible for finding space for a  $\mathbf{U}$ . The caller may simply ask for the space to the memory allocator, in which case we’ve saved nothing; but it can also reuse the space of an existing  $\mathbf{U}$  which it doesn’t need anymore, or space in an array, or even space in a region of memory that the allocator doesn’t have access to, like a memory-mapped file. In fact, as we’ll see in Section 2.5, destination-passing style is always more general than its direct style counterpart (though it might be slightly more verbose); there are no drawbacks to use it as we can always recover regular direct style functions in a systematic way from the destination-passing ones.

So far we mostly considered destination passing in imperative contexts, such as systems programming, but we argue that destination passing also presents many benefits for functional programming languages, even pure ones. Where destinations truly shine in functional programming is that they let us borrow imperative-like programming techniques to get a more expressive language, with more control over processing, and with careful attention, we can still preserve the nice properties of functional languages such as purity and (apparent) immutability.

Thus, the goal here will be to modify a standard functional programming language just enough to be able to build immutable structures by destination passing without endangering purity and memory safety. Destinations in this particular setting become *write-once-only* references into a structure that contains holes and that cannot be read yet. Quite more restrictive than C pointers (that can be used in read and write fashion without restrictions), but still powerful enough to bring new programming techniques into the functional world.

More precisely, there are two key elements that contribute to the extra expressiveness of destination passing in functional contexts:

- structures can be built in any order. Not only from the leaves to the root, like in ordinary functional programming, but also from the root to the leaves, or any combination thereof. This can be done in ordinary functional programming using function composition in a form of continuation-passing; however destinations act as a very direct optimization of this scheme. This line of work was pioneered by Minamide [1998];
- when destinations are first-class values, they can be passed and stored like ordinary values. The consequence is not only that the order in which a structure is built is arbitrary, but also that this order can be determined dynamically during the runtime of the program. Here is the main novelty of our approach compared to earlier work.

In this chapter, we introduce  $\lambda_d$ , a pure functional calculus that is based on the very concept of destinations at its core. We intend  $\lambda_d$  to serve as a foundational, theoretical calculus to reason about safe destinations in a functional setting; thus, we will only cover very briefly the implementation concerns in this chapter, as  $\lambda_d$  is not really meant to be implemented as a real programming language. Actual implementation of destination passing in an existing functional language will be the focus of the next chapters.

$\lambda_d$  subsumes all the functional systems with destinations from the literature, from [Minamide, 1998] to [Lorenzen, Leijen, Swierstra, and Lindley, 2024]. As such we expect that these systems or their extensions can be justified simply by giving them a translation into  $\lambda_d$ , in order to get all the safety results and metatheory of  $\lambda_d$  for free. Indeed, we proved type safety theorems for  $\lambda_d$  with the Coq proof assistant, as described in Section 2.7.

## 2.2 Working with destinations in $\lambda_d$

Let's introduce and get familiar with  $\lambda_d$ , a modal, linear, simply typed  $\lambda$ -calculus with destinations. We borrow most of the syntax of the previous chapter, especially from  $\lambda_{Ldm}$ . We still use linear logic's  $\mathbf{T} \oplus \mathbf{U}$  and  $\mathbf{T} \otimes \mathbf{U}$  for sums and products, and linear function arrow  $\multimap$ , since  $\lambda_d$  is linearly typed. The main difference with previous calculi being that  $\lambda_d$  doesn't have first-class data constructors like  $\text{Inl } t$  or  $(t_1, t_2)$ , as they are replaced with the more general destination-filling operators that we'll discover in the next paragraphs.

### 2.2.1 Building up a vocabulary

In its simplest form, destination passing, much like continuation passing, is using a location, received as an argument, to write the output value instead of returning it proper. For instance, the following is a destination-passing version of the identity function:

**dId** :  $\mathbb{T} \multimap [\mathbb{T}] \multimap 1$   
**dId**  $x\ d \triangleq d \blacktriangleleft x$

We can think of a destination as a reference to an uninitialized memory location, and  $d \blacktriangleleft x$  (read “fill  $d$  with  $x$ ”) as writing  $x$  to the memory location pointed to by  $d$ .

Performing  $d \blacktriangleleft x$  is the simplest way to use a destination: with that we fill it with a value directly. But we can also fill a destination piecewise, by specifying just the outermost constructor that we want to fill it with:

**fillWithInl** :  $[\mathbb{T} \oplus \mathbb{U}] \multimap [\mathbb{T}]$   
**fillWithInl**  $d \triangleq d \triangleleft \text{Inl}$

In this example, we’re filling a destination for type  $\mathbb{T} \oplus \mathbb{U}$  by setting the outermost constructor to left variant **Inl**. We think of  $d \triangleleft \text{Inl}$  (read “fill  $d$  with **Inl**”) as allocating memory to store a block of the form **Inl**  $\square$ , and write the address of that block to the location that  $d$  points to. Because we’ve just created an **Inl** constructor with no argument yet, we return a new destination of type  $[\mathbb{T}]$  pointing to the uninitialized argument of **Inl**. Uninitialized memory, when part of a structure or value, like  $\square$  in **Inl**  $\square$ , is called a *hole*.

Notice that with **fillWithInl** we are constructing the structure from the outermost constructor inward: we’ve written a value of the form **Inl**  $\square$  into a hole, but we have yet to describe what goes in the new hole  $\square$ . Such data constructors with uninitialized arguments are called *hollow constructors*<sup>10</sup>. This is opposite to how functional programming usually works, where values are built from the innermost constructors outward: first we build a value  $v$  and only then can we use **Inl** to make **Inl**  $v$ . Being able to build structures from the outermost constructor inward is a key ingredient to the extra expressiveness that we promised earlier.

Yet, everything we’ve shown so far could, in principle, have been expressed using continuations. So it’s worth asking: how exactly are destinations different from continuations? Part of the answer lies in our intention to effectively implement destinations as pointers to uninitialized memory (see Section 2.9 but also Chapters 3 and 4). But where destinations really differ from continuations is that we can easily split a destination for a data structure into several destinations for each of its parts. Then, the user is required to fill *all* the resulting destinations. One example of such splitting is the **fillWithPair** function, which writes a hollow pair constructor into a destination:

**fillWithPair** :  $[\mathbb{T} \otimes \mathbb{U}] \multimap [\mathbb{T}] \otimes [\mathbb{U}]$   
**fillWithPair**  $d \triangleq d \triangleleft (,)$

After using **fillWithPair**, both the first field *and* the second field of the pair must be filled, using the returned destinations of type  $[\mathbb{T}]$  and  $[\mathbb{U}]$  respectively.

<sup>10</sup>The full triangle  $\blacktriangleleft$  is used to fill a destination with a fully-formed value, while the *hollow* triangle  $\triangleleft$  is used to fill a destination with a *hollow constructor*.

In contrast, a continuation-passing style equivalent of **fillWithPair** would need signature  $(\mathbf{T} \otimes \mathbf{U} \multimap \mathbf{S}) \multimap (\mathbf{T} \multimap \mathbf{S}) \otimes (\mathbf{U} \multimap \mathbf{S})$  (this is different from the usual CPS encoding of the pair constructor with signature  $(\mathbf{T} \otimes \mathbf{U} \multimap \mathbf{S}) \multimap (\mathbf{T} \multimap \mathbf{S}) \otimes (\mathbf{U} \multimap \mathbf{S})$ ). In fact **fillWithPairCPS** :  $(\mathbf{T} \otimes \mathbf{U} \multimap \mathbf{S}) \multimap (\mathbf{T} \multimap \mathbf{S}) \otimes (\mathbf{U} \multimap \mathbf{S})$  cannot be defined, as we would need to collect the results of the two created continuations before we can consume the input continuation of type  $(\mathbf{T} \otimes \mathbf{U} \multimap \mathbf{S})$  (thus requiring a form of synchronization and state-passing).

Similarly to continuation-passing transformation though, we can already note that there is a sort of duality between destination-filling operators and the corresponding data constructors. Usual **Inl** constructor has signature  $\mathbf{T} \multimap \mathbf{T} \oplus \mathbf{U}$ , while destination-filling  $\triangleleft \mathbf{Inl}$  has signature  $[\mathbf{T} \oplus \mathbf{U}] \multimap [\mathbf{T}]$ . Similarly, pair constructor  $(\cdot)$  has signature  $\mathbf{T} \multimap \mathbf{U} \multimap \mathbf{T} \otimes \mathbf{U}$ , while destination-filling  $\triangleleft (\cdot)$  has signature  $[\mathbf{T} \otimes \mathbf{U}] \multimap [\mathbf{T}] \otimes [\mathbf{U}]$ . Assuming some flexibility with currying, we see that the types of arguments and results switch sides around the arrow, and get wrapped/unwrapped from  $[\cdot]$  when we go from the constructor to the destination-filling operator and vice-versa. This observation will generalize to all destination-filling operators and the corresponding constructors.

**Structures with holes** It is crucial to note that while a destination is used to build a structure, the destination refers only to a specific part of the structure that hasn't been defined yet; not the structure as a whole. Consequently, the (root) type of the structure being built will often be different from the type of the destination at hand. A destination of type  $[\mathbf{T}]$  only indicates that some bigger structure has at least a hole of type  $\mathbf{T}$  somewhere in it. The type of the structure itself never appears in the signature of destination-filling functions (for instance, using **fillWithPair** only indicates that the structure being operated on has a hole of type  $\mathbf{T} \otimes \mathbf{U}$  that is being written to).

Thus, we still need a type to tie the structure under construction —left implicit by destination-filling primitives— with the destinations representing its holes. To represent this,  $\lambda_d$  introduces a type  $\mathbf{S} \ltimes [\mathbf{T}]$  for a structure of type  $\mathbf{S}$  missing a value of type  $\mathbf{T}$  to be complete. There can be several holes in  $\mathbf{S}$  —resulting in several destinations on the right hand side— and as long as there remain holes in  $\mathbf{S}$ , it cannot be read. For instance,  $\mathbf{S} \ltimes ([\mathbf{T}] \otimes [\mathbf{U}])$  represents an  $\mathbf{S}$  that misses both a  $\mathbf{T}$  and a  $\mathbf{U}$  to be complete (thus to be readable). The right hand side of  $\ltimes$  is not restricted to pair and destination types only; it can be of arbitrarily complex type.

The general form  $\mathbf{S} \ltimes \mathbf{T}$  is read “ $\mathbf{S}$  ampar  $\mathbf{T}$ ”. The name “ampar” stands for “asymmetric memory par”. The “par”  $\wp$  operator originally comes from (classical) linear logic, and is an associative and commutative operator that can be used in place of linear implication and is slightly more flexible:  $\mathbf{T} \multimap \mathbf{S}$  is equivalent to  $\mathbf{T}^\perp \wp \mathbf{S}$  or  $\mathbf{S} \wp \mathbf{T}^\perp$ . Similarly,  $\mathbf{T}_1 \multimap \mathbf{T}_2 \multimap \mathbf{S}$  is equivalent to  $\mathbf{T}_1^\perp \wp \mathbf{T}_2^\perp \wp \mathbf{S}$ . Function input's types —which are in negative position— are wrapped in the dualizing operator  $\cdot^\perp$  when a function is put into “par” form. Here we take a similar approach: Minamide [1998] first observed that structures with holes are akin to linear functions  $\mathbf{T} \multimap \mathbf{S}$ , where  $\mathbf{T}$  represents the missing part; so we decide to represent them in a more flexible fashion under the form  $\mathbf{S} \ltimes [\mathbf{T}]$ . In this presentation, the *missing part of type  $\mathbf{T}$*  appears as a first-class type  $[\mathbf{T}]$ , a.k.a the *destination* type. The asymmetric nature of our memory par is an unfortunate byproduct of wanting simple sequential semantics. Indeed, it seems that having a symmetric memory par would require concurrent semantics, as the structure being constructed and the destinations pointing to it could be consumed alike, meaning that we could have to pause and wait for a hole to be filled<sup>11</sup>.

<sup>11</sup>[DeYoung, Pfenning, and Pruiksmā, 2020] features such a system with destinations and a concurrent execution model

Destinations, albeit being first-class, always exist within the context of a structure with holes. A destination is both a witness of a hole present in the structure, and a handle to write to it. Crucially, destinations are otherwise ordinary values that lives in the right side of the corresponding ampar. To access the destinations of an ampar,  $\lambda_d$  provides a  $\text{upd}_\times$  construction, which lets us apply a function to the right-hand side of the ampar. It is in the body of  $\text{upd}_\times : \mathbf{S} \times \mathbf{T} \multimap (\mathbf{T} \multimap \mathbf{U}) \multimap \mathbf{S} \times \mathbf{U}$  that functions operating on destinations can be called to update the structure:

$$\begin{aligned} \text{fillWithInl}' &: \mathbf{S} \times [\mathbf{T} \oplus \mathbf{U}] \multimap \mathbf{S} \times [\mathbf{T}] \\ \text{fillWithInl}' x &\triangleq \text{upd}_\times x \text{ with } d \mapsto d \triangleleft \text{Inl} \\ \text{fillWithPair}' &: \mathbf{S} \times [\mathbf{T} \otimes \mathbf{U}] \multimap \mathbf{S} \times ([\mathbf{T}] \otimes [\mathbf{U}]) \\ \text{fillWithPair}' x &\triangleq \text{upd}_\times x \text{ with } d \mapsto \text{fillWithPair } d \end{aligned}$$

To tie this up, we need a way to introduce and to eliminate structures with holes. Structures with holes are introduced with  $\text{new}_\times$  which creates a value of type  $\mathbf{T} \times [\mathbf{T}]$ .  $\text{new}_\times$  is somewhat similar to the linear identity function: it is a hole (of type  $\mathbf{T}$ ) that needs a value of type  $\mathbf{T}$  to be a complete value of type  $\mathbf{T}$ . Memory-wise, it is an uninitialized block large enough to host a value of type  $\mathbf{T}$ , and a destination pointing to it. Conversely, structures with holes are eliminated with<sup>12</sup>  $\text{from}'_\times : \mathbf{S} \times \mathbf{1} \multimap \mathbf{S}$ : if all the destinations have been consumed and only unit remains on the right side, then  $\mathbf{S}$  no longer has holes and thus is just a normal data structure.

Equipped with these new operators, we can finally show how to derive traditional constructors from piecemeal filling. Indeed, as we said earlier,  $\lambda_d$  doesn't have primitive constructor forms; constructors in  $\lambda_d$  are syntactic sugar. We show here the definition of  $\text{Inl}$  and  $(,)$ , but the other constructors are derived similarly. Operator  $\mathbin{;} : \mathbf{1} \multimap \mathbf{U} \multimap \mathbf{U}$ , present in second example, is used to chain operations returning unit type  $\mathbf{1}$ . For easier reading, we also provide type annotation when  $\text{new}_\times$  is used:

$$\begin{aligned} \text{Inl} &: \mathbf{T} \multimap \mathbf{T} \oplus \mathbf{U} \\ \text{Inl } x &\triangleq \text{from}'_\times (\text{upd}_\times (\text{new}_\times : (\mathbf{T} \oplus \mathbf{U}) \times [\mathbf{T} \oplus \mathbf{U}]) \text{ with } d \mapsto d \triangleleft \text{Inl} \triangleleft x) \\ (,) &: \mathbf{T} \multimap \mathbf{U} \multimap \mathbf{T} \otimes \mathbf{U} \\ (x, y) &\triangleq \text{from}'_\times (\text{upd}_\times (\text{new}_\times : (\mathbf{T} \otimes \mathbf{U}) \times [\mathbf{T} \otimes \mathbf{U}]) \text{ with } d \mapsto \text{case } (d \triangleleft (,)) \text{ of } (d_1, d_2) \mapsto d_1 \triangleleft x \mathbin{;} d_2 \triangleleft y) \end{aligned}$$

**Memory safety and purity** We must reassure the reader here. Of course, using destinations in an unrestricted fashion is not memory safe. We need a linear discipline on destinations for them to be safe. Otherwise, we can encounter two sorts of issues:

- if destinations are not written at least once, as in:

$$\begin{aligned} \text{forget} &: \mathbf{T} \\ \text{forget} &\triangleq \text{from}'_\times (\text{upd}_\times (\text{new}_\times : \mathbf{T} \times [\mathbf{T}]) \text{ with } d \mapsto ()) \end{aligned}$$

then reading the result of **forget** would lead to reading a location pointed to by a destination that we never used, in other words, reading uninitialized memory. This must be prevented at all cost;

<sup>12</sup>As the name suggest, there is a more general elimination  $\text{from}_\times$ . It will be discussed in Section 2.5.

- if destinations are written several times, as in:

```

ambiguous1 : Bool
ambiguous1  $\triangleq$  from'×(upd×(new× : Bool × [Bool]) with  $d \mapsto d \blacktriangleleft \text{true} \ ; \ d \blacktriangleleft \text{false}$ )

ambiguous2 : Bool
ambiguous2  $\triangleq$  from'×(upd×(new× : Bool × [Bool]) with  $d \mapsto \text{let } x := (d \blacktriangleleft \text{false}) \text{ in } d \blacktriangleleft \text{true} \ ; \ x$ )

```

then, we have **ambiguous1** that returns false and **ambiguous2** that returns true due to evaluation order, so we break *let expansion* that is supposed to be valid in a pure language (including  $\lambda_d$ ).

Actually, we'll see in Section 2.3 that a linear discipline is not even enough to ensure fully safe use of destinations in  $\lambda_d$ . But before dealing with this, let's get more familiar with  $\lambda_d$  through more complex examples.

### 2.2.2 Tail-recursive map

Let's see how destinations can be used to build usual data structures. For these examples, we suppose that  $\lambda_d$  has equirecursive types and a fixed-point operator (though this isn't included in the formal system of Section 2.5).

**Linked lists** We define lists as a fixpoint, as usual: **List**  $T \triangleq 1 \oplus (T \otimes (\text{List } T))$ . For convenience, we also define filling operators  $\blacktriangleleft[]$  and  $\blacktriangleleft(::)$ , as macros that use the primitive destination-filling operators for sum, product and unit types:

$\blacktriangleleft[] : [\text{List } T] \multimap 1$ $d \blacktriangleleft[] \triangleq d \blacktriangleleft \text{Inl } \blacktriangleleft()$	$\blacktriangleleft(::) : [\text{List } T] \multimap [T] \otimes [\text{List } T]$ $d \blacktriangleleft(::) \triangleq d \blacktriangleleft \text{Inr } \blacktriangleleft(,)$
--	--

Just like we did in Section 2.2.1 we can recover traditional constructors systematically from destination-filling operators, using **new**<sub>×</sub>, **upd**<sub>×</sub> and **from'**<sub>×</sub>:

```

(::) : T ⊗ (List T)  $\multimap$  List T
x :: xs  $\triangleq$  from'×(upd×(new× : (List T) × [List T]) with  $d \mapsto$ 
    case ( $d \blacktriangleleft (::)$ ) of ( $dx, dxs$ )  $\mapsto dx \blacktriangleleft x \ ; \ dxs \blacktriangleleft xs$ )

```

**A tail-recursive map function** List being ubiquitous in functional programming, the fact that the most natural way to write a **map** function on lists isn't tail recursive (hence consumes unbounded stack space), is unpleasant. Map can be made tail-recursive in two passes: first build the result list in reverse order, then reverse it. But thanks to destinations, we are able to avoid this two-pass process altogether, as they let us extend the tail of the result list directly. We give the complete implementation in Listing 2.1.

The tail-recursive function is **map'**, it has type  $(T \multimap U) \multimap \text{List } T \multimap [\text{List } U] \multimap 1$ <sup>13</sup>. That is, instead of returning a resulting list, it takes a destination as an input and fills it with the result. At each recursive call, **map'** creates a new hollow cons cell to fill the destination. A destination

<sup>13</sup>In fact, we'll develop a more complex system of modes starting from Section 2.5 to ensure scope control of destinations, and thus the proper signature will be  $(T \multimap U) \multimap \text{List } T \multimap [\text{List } U] \multimap 1$ .

```

List T  $\triangleq$   $1 \oplus (\mathbf{T} \otimes (\mathbf{List} \ \mathbf{T}))$ 
map' :  $(\mathbf{T} \multimap \mathbf{U}) \multimap \mathbf{List} \ \mathbf{T} \multimap [\mathbf{List} \ \mathbf{U}] \multimap 1$ 
map' f l dl  $\triangleq$ 
  case l of {
    []  $\mapsto$  dl  $\triangleleft$  [],
    x :: xs  $\mapsto$  case (dl  $\triangleleft$  (::)) of
      (dx, dxs)  $\mapsto$  dx  $\blacktriangleleft$  f x ; map' f xs dxs }
map :  $(\mathbf{T} \multimap \mathbf{U}) \multimap \mathbf{List} \ \mathbf{T} \multimap \mathbf{List} \ \mathbf{U}$ 
map f l  $\triangleq$  from' $\times$ (upd $\times$ (new $\times$  : ( $\mathbf{List} \ \mathbf{U}$ )  $\times$  [ $\mathbf{List} \ \mathbf{U}$ ]) with dl  $\mapsto$  map' f l dl)

```

Listing 2.1: Tail-recursive **map** function on lists

pointing to the tail of the new cons cell is also created, on which **map'** is called (tail) recursively. This is really the same algorithm that you could write to implement map on a mutable list in an imperative language. Nevertheless  $\lambda_d$  is a pure language with only immutable types<sup>14</sup>.

To obtain the regular **map** function, all is left to do is to call **new** <sub>$\times$</sub>  to create an initial destination, and **from'** <sub>$\times$</sub>  when all destinations have been filled to extract the completed list; much like when we make constructors out of filling operators, like (::) above.

### 2.2.3 Functional queues, with destinations

Implementations for a tail-recursive map are present in most of the previous works, from [Minamide, 1998], to recent work [Bour, Clément, and Scherer, 2021; Leijen and Lorenzen, 2025]. Tail-recursive map doesn't need the full power of  $\lambda_d$ 's first-class destinations: it just needs a notion of structure with a (single) hole. We'll slowly works towards an example which uses first-class destinations at their full potential.

**Difference lists** Just like in any programming language, the iterated concatenation of linked lists  $((xs_1 ++ xs_2) ++ \dots) ++ xs_n$  is quadratic in  $\lambda_d$ . The usual solution to improve this complexity is to use *difference lists*. The name *difference lists* covers many related implementations for the concept of a “linked list missing a queue”. The idea is that a difference list carries the same elements as a list would, but can be easily extended by the back in constant time as we retain a way to set a value for its queue later. In pure functional languages, a difference list is usually represented as a function instead [Hughes, 1986], as we usually don't have write pointers. A singleton difference list is then  $\lambda ys \mapsto x :: ys$ , and concatenation of difference lists is function composition. A difference list is turned into a list by setting its queue to be the empty list, or in the functional case, by applying it to the empty list. The consequence is that no matter how many compositions we have, each cons cell will be allocated a single time, making the iterated concatenation linear indeed.

The problem is that in the functional implementation, each concatenation still allocates a closure. If we're building a difference list from singletons and composition, there's roughly one composition per cons cell, so iterated composition effectively performs two traversals of the

<sup>14</sup>We consider data structures in  $\lambda_d$  to be immutable thanks to the fact that structure with holes cannot be scrutinized while they haven't been fully completed, so destination-related mutations are completely opaque and unobservable.

<pre> DList T <math>\triangleq</math> (List T) <math>\times</math> [List T] append : DList T <math>\multimap</math> T <math>\multimap</math> DList T ys append y <math>\triangleq</math>   upd<math>_{\times}</math> ys with dys <math>\mapsto</math> case (dys <math>\triangleleft</math> (::)) of     (dy, dys') <math>\mapsto</math> dy <math>\blacktriangleleft</math> y <math>\circ</math> dys' concat : DList T <math>\multimap</math> DList T <math>\multimap</math> DList T ys concat ys' <math>\triangleq</math> upd<math>_{\times}</math> ys with d <math>\mapsto</math> d <math>\triangleleft</math> ys' toList : DList T <math>\multimap</math> List T toList ys <math>\triangleq</math> from'<math>_{\times}</math>(upd<math>_{\times}</math> ys with d <math>\mapsto</math> d <math>\triangleleft</math> [])         </pre>	<pre> Queue T <math>\triangleq</math> (List T) <math>\otimes</math> (DList T) singleton : T <math>\multimap</math> Queue T singleton x <math>\triangleq</math> (Inr (x :: []), (new<math>_{\times}</math> : DList T)) enqueue : Queue T <math>\multimap</math> T <math>\multimap</math> Queue T q enqueue y <math>\triangleq</math>   case q of (xs, ys) <math>\mapsto</math> (xs, ys append y) dequeue : Queue T <math>\multimap</math> 1 <math>\oplus</math> (T <math>\otimes</math> (Queue T)) dequeue q <math>\triangleq</math>   case q of {     ((x :: xs), ys) <math>\mapsto</math> Inr (x, (xs, ys)),     ([], ys) <math>\mapsto</math> case (toList ys) of {       [] <math>\mapsto</math> Inl (),       x :: xs <math>\mapsto</math> Inr (x, (xs, (new<math>_{\times}</math> : DList T))) }   }         </pre>
---	--

Listing 2.2: Difference list and queue implementation in equirecursive  $\lambda_d$

list. In  $\lambda_d$ , we actually have write pointers, in the form of *destinations*, so we can do better by representing a difference list as a list with a hole, much like in an imperative setting. A singleton difference list becomes  $x::\square$ , and concatenation is filling the hole with another difference list, using composition operator  $\triangleleft$ . The detailed implementation is given on the left of Listing 2.2. This encoding for difference lists makes no superfluous traversal: concatenation is just an  $O(1)$  in-place update.

**Efficient queue using difference lists** In an immutable functional language, a queue can be implemented as a pair of lists (*front*, *back*) [Hood and Melville, 1981]. The list *back* stores new elements in reverse order ( $O(1)$  prepend). We pop elements from *front*, except when it is empty, in which case we set the queue to (**reverse back**, []), and pop from the new front.

For their simple implementation, Hood-Melville queues are surprisingly efficient: the cost of the reverse operation is  $O(1)$  amortized for a single-threaded use of the queue. Still, it would be better to get rid of this full traversal of the back list. Taking a step back, this *back* list that has to be reversed before it is accessed is really merely a representation of a list that can be extended from the back. And we already know an efficient implementation for this: difference lists.

So we can give an improved version of the simple functional queue using destinations. This implementation is presented on the right-hand side of Listing 2.2. Note that contrary to an imperative programming language, we can't implement the queue as a single difference list: as mentioned earlier, our type system prevents us from reading the front elements of difference lists. Just like for the simple functional queue, we need a pair of one list that we can read from, and one that we can extend. Nevertheless this implementation of queues is both pure, as guaranteed by the  $\lambda_d$  type system, and nearly as efficient as what an imperative programming language would afford.

## 2.3 Scope escape of destinations

In Section 2.2, we made an implicit assumption: establishing a linear discipline on destinations ensures that all destinations will eventually find their way to the left of a fill operator  $\blacktriangleleft$  or  $\triangleleft$ , so that the associated holes get written to. This turns out to be slightly incomplete.

To see why, let's consider the type  $\llbracket \mathbf{T} \rrbracket$ : the type of a destination pointing to a hole where a destination is expected. Think of it as an equivalent of the pointer type  $\mathbf{T}^{**}$  in the C language. Destinations are indeed ordinary values, so they can be stored in data structures, and before they get stored, holes stand in their place in the structure. For instance, if we have  $d : \llbracket \mathbf{T} \rrbracket$  and  $dd : \llbracket \llbracket \mathbf{T} \rrbracket \rrbracket$ , we can form  $dd \blacktriangleleft d$ :  $d$  will be stored in the structure pointed to by  $dd$ .

Should we count  $d$  as linearly used here? The alternatives don't seem promising:

- If we count this as a non-linear use of  $d$ , then  $dd \blacktriangleleft d$  is rejected since destinations (like  $d$  here) can only be used linearly. This choice is fairly limiting, as it would prevent us from storing destinations in structures with holes, as we will do, crucially, in Section 2.4.
- If we do not count this use of  $d$  at all, we can write  $dd \blacktriangleleft d \ ; \ d \blacktriangleleft v$  so that  $d$  is both stored for later use *and* filled immediately (resulting in the corresponding hole being potentially written to twice), which is unsound, as discussed at the end of Section 2.2.1.

So linear use it is. But this creates a problem: there's no way, within our linear type system, to distinguish between “a destination that has been used on the left of a triangle so its corresponding hole has been filled” and “a destination that has been stored and its hole still exists at the moment”. This oversight may allow us to read uninitialized memory!

Let's compare two examples. We assume a simple store semantics for now where structures with holes stay in the store until they are completed. A reduction step goes from a pair  $\mathcal{S}|t$  of a store and a term to a new pair  $\mathcal{S}'|t'$ , and store are composed of named bindings of the form  $\{l := v\}$  with  $v$  a value that may contain holes. We'll also need the  $\mathbf{alloc} : (\llbracket \mathbf{T} \rrbracket \multimap \mathbf{1}) \multimap \mathbf{T}$  operator. The semantics of  $\mathbf{alloc}$  is: allocate a structure with a single root hole in the store, call the supplied function with the destination to the root hole as an argument; when the function has consumed all destinations (so only unit remains), pop the structure from the store to obtain a complete  $\mathbf{T}$ .  $\mathbf{alloc} f$  corresponds, in type and behavior, to  $\mathbf{from}'_{\times}(\mathbf{upd}_{\times} \mathbf{new}_{\times} \text{ with } d \mapsto f d)$ .

In the following snippets, structures with holes are given names  $l$  and  $ld$  in the store; holes are given names too and denoted by  $\boxed{h}$  and  $\boxed{hd}$ , and concrete destinations are denoted by  $\rightarrow h$  and  $\rightarrow hd$ .

When the building scope of  $l : \mathbf{Bool}$  is parent to the one of  $ld : \llbracket \mathbf{Bool} \rrbracket$ , everything works well because  $ld$ , that contains destination pointing to  $\boxed{h}$ , has to be consumed before  $l$  can be read. In other terms, storing an older destination into a fresher one is not a problem:

$$\begin{aligned}
& \{ \} \mid \mathbf{alloc} (\lambda d \mapsto (\mathbf{alloc} (\lambda dd \mapsto dd \blacktriangleleft d) : \llbracket \mathbf{Bool} \rrbracket) \blacktriangleleft \mathbf{true}) \\
\longrightarrow & \{l := \boxed{h}\} \mid (\mathbf{alloc} (\lambda dd \mapsto dd \blacktriangleleft \rightarrow h) : \llbracket \mathbf{Bool} \rrbracket) \blacktriangleleft \mathbf{true} \ ; \ \mathbf{deref} \ l \\
\longrightarrow & \{l := \boxed{h}, ld := \boxed{hd}\} \mid (\rightarrow hd \blacktriangleleft \rightarrow h \ ; \ \mathbf{deref} \ ld) \blacktriangleleft \mathbf{true} \ ; \ \mathbf{deref} \ l \\
\longrightarrow & \{l := \boxed{h}, ld := \rightarrow h\} \mid \mathbf{deref} \ ld \blacktriangleleft \mathbf{true} \ ; \ \mathbf{deref} \ l \\
\longrightarrow & \{l := \boxed{h}\} \mid \rightarrow h \blacktriangleleft \mathbf{true} \ ; \ \mathbf{deref} \ l \\
\longrightarrow & \{l := \mathbf{true}\} \mid \mathbf{deref} \ l \\
\longrightarrow & \{ \} \mid \mathbf{true}
\end{aligned}$$

However, when  $ld$ 's scope is parent to  $l$ 's, i.e. when a newer destination is stored into an older one, then we can write a linearly typed yet unsound program:

$$\begin{aligned}
 & \{ \} \mid \text{alloc } (\lambda dd \mapsto \text{case } (\text{alloc } (\lambda d \mapsto dd \blacktriangleleft d) : \text{Bool}) \text{ of } \{ \text{true} \mapsto (), \text{false} \mapsto () \}) \\
 \longrightarrow & \{ ld := \boxed{hd} \} \mid \text{case } (\text{alloc } (\lambda d \mapsto \rightarrow hd \blacktriangleleft d) : \text{Bool}) \text{ of } \{ \text{true} \mapsto (), \text{false} \mapsto () \} \ ; \ \text{deref } ld \\
 \longrightarrow & \{ ld := \boxed{hd}, l := \boxed{h} \} \mid \text{case } (\rightarrow hd \blacktriangleleft \rightarrow h \ ; \ \text{deref } l) \text{ of } \{ \text{true} \mapsto (), \text{false} \mapsto () \} \ ; \ \text{deref } ld \\
 \longrightarrow & \{ ld := \rightarrow h, l := \boxed{h} \} \mid \text{case } (\text{deref } l) \text{ of } \{ \text{true} \mapsto (), \text{false} \mapsto () \} \ ; \ \text{deref } ld \\
 \longrightarrow & \{ ld := \rightarrow h \} \mid \text{case } \boxed{h} \text{ of } \{ \text{true} \mapsto (), \text{false} \mapsto () \} \ ; \ \text{deref } ld \quad \bullet\bullet\bullet
 \end{aligned}$$

Here the expression  $dd \blacktriangleleft d$  results in  $d$  escaping its scope for the parent one, so  $l$  is just uninitialized memory (the hole  $\boxed{h}$ ) when we dereference it. This example must be rejected by our type system.

A neighboring issue is when sibling destinations interact with one another:

$$\begin{aligned}
 & \{ \} \mid \text{alloc } (\lambda d \mapsto \text{case } (d \blacktriangleleft (::)) \text{ of } (d' : \text{Bool}, dd' : \llbracket \text{Bool} \rrbracket) \mapsto dd' \blacktriangleleft d') : \text{Bool} \otimes \llbracket \text{Bool} \rrbracket \\
 \longrightarrow & \{ l := \boxed{h} \} \mid \text{case } (\rightarrow h \blacktriangleleft (::)) \text{ of } (d' : \text{Bool}, dd' : \llbracket \text{Bool} \rrbracket) \mapsto dd' \blacktriangleleft d' \ ; \ \text{deref } l \\
 \longrightarrow & \{ l := (\boxed{h'}, \boxed{hd'}) \} \mid \text{case } (\rightarrow h', \rightarrow hd') \text{ of } (d' : \text{Bool}, dd' : \llbracket \text{Bool} \rrbracket) \mapsto dd' \blacktriangleleft d' \ ; \ \text{deref } l \\
 \longrightarrow & \{ l := (\boxed{h'}, \boxed{hd'}) \} \mid \rightarrow hd' \blacktriangleleft \rightarrow h' \ ; \ \text{deref } l \\
 \longrightarrow & \{ l := (\boxed{h'}, \rightarrow h') \} \mid \text{deref } l \\
 \longrightarrow & \{ \} \mid (\boxed{h'}, \rightarrow h') \quad \bullet\bullet\bullet
 \end{aligned}$$

Here also, we have a hole  $\boxed{h'}$  escaping from the store, which means that if we pattern-match on the result of the code block above, we will also end up reading uninitialized memory!

Again, the problem is that, using purely a linear type system, we can only reject the two last examples if we also reject the first, sound one. In this case, the type  $\llbracket \text{T} \rrbracket$  would become practically useless: such destinations could never be filled. This isn't the direction we want to take: we really want to be able to store destinations in data structures with holes. So we want  $t$  in  $d \blacktriangleleft t$  to be allowed to be linear. Without further restrictions, it wouldn't be sound, so to address this, we need an extra control system to prevent scope escape; it can't be just linearity. More specifically, we must ensure that if a destination  $d$  is stored inside another destination  $dd$ , then  $d$  originates from a scope that is strictly older—that is, one that was opened strictly before the scope of  $dd$ . This condition rules out the two problematic examples we have just discussed.

For  $\lambda_d$ , we decided to use a system of *ages* to represent which scope a resource originates from. Ages are described in detail in Section 2.5. In the rest of this document, we often refer to *scope escape* to indistinctly designate the two issues presented above: either the case  $dd \blacktriangleleft d$  where  $d$  comes from a strictly younger scope, or the case where  $d$  comes from the same scope as  $dd$ , as both are often avoided using the same techniques or tricks.

**General considerations on linearity, scopes, and references** Scope escape, as just described, is not an issue specific to destinations. In fact, it seems that any form of storage, be it destinations, or refs *à la* OCaml, or anything that can be written to, may act as a channel through which scope escape can occur, if it is given a linear interface.

Conversely, scope escape poses a risk not only to destinations but to most linear resources. Linear interfaces typically rely on the fact that there is a specific set of destructor-like functions for a given resource type, and that we want one of them to be called for each resource at some point. Linearity forces us to consume the resource in the scope it is made available, and if the resource type is opaque, then the only way to consume it is by eventually calling one of these destructors, as expected. However, linear storage undermines this assumption by faking resource consumption without immediately invoking a destructor.

## 2.4 Breadth-first tree traversal

Before turning to the formal details, let us look at a full-fledged example, which uses the whole expressive power of  $\lambda_d$ . We focus here on breadth-first tree relabeling: “*Given a tree, create a new one of the same shape, but with the values at the nodes replaced by the numbers  $1 \dots |T|$  in breadth-first order.*”

This isn’t a very natural problem for functional programming, as breadth-first traversal implies that the order in which the structure must be built (left-to-right, top-to-bottom) is not the same as the structural order of a functional tree —building the leaves first and going up to the root. So it usually requires fancy functional workarounds [Gibbons, 1993; Okasaki, 2000; Gibbons et al., 2023].

We may feel drawn to solve this exercise in an efficient imperative-like fashion, where a queue drives the processing order. That’s the standard algorithm taught at university, where the next node to process is dequeued from the front of the queue, and its children nodes are enqueued at the back of the queue for later processing, achieving breadth-first traversal. For that, Minamide’s system [Minamide, 1998] where structures with holes are represented as linear functions cannot help. We really need destinations as first-class values to borrow from this imperative power.

Listing 2.3 presents how we can implement this breadth-first tree traversal in  $\lambda_d$ , thanks to first-class destinations. We assume the data type **Tree T** has been defined, unsurprisingly, as **Tree T**  $\triangleq 1 \oplus (T \otimes ((\text{Tree T}) \otimes (\text{Tree T})))$ ; and we refer to the constructors of **Tree T** as **Nil** and **Node**, defined as syntactic sugar as we did for the other constructors before. We also assume some encoding of the type **Nat** of natural numbers. Remember that **Queue T** is the efficient queue type from Section 2.2.3.

The core idea of our algorithm is that we hold a queue of pairs, storing each an input subtree and (a destination to) its corresponding output subtree. When the element  $(tree, dtree)$  at the front of the queue has been processed, the children nodes of  $tree$  and children destinations of  $dtree$  are enqueued to be processed later, much as the original imperative algorithm.

We implement the actual breadth-first relabeling **relabelDps** as an instance of a more general breadth-first traversal function **mapAccumBfs**, which applies any state-passing style transformation of labels in breadth-first order. In **mapAccumBfs**, we create a new destination  $dtree$  into which we will write the result of the traversal, then call **go**. The **go** function is in destination-passing style, but what’s remarkable is that **go** takes an unbounded number of destinations as arguments, since there are as many destinations as items in the queue. This is where we use the fact that destinations are ordinary values.

This freshly gained expressivity has a cost though: we need a type system that combines linearity control *and* age control to make the system sound, otherwise we run into the issues of scope escape described in the previous section. We’ll combine both linearity and the aforementioned ages system in the same *mode ringoid*<sup>15</sup>. You already know the linearity annotations **1** and  $\omega$  from Chapter 1; here we also introduce the new age annotation  $\infty$ , that indicates that the associated argument cannot carry destinations. Arguments with no modes displayed on them, or function arrows with no modes, default to the unit of the ringoid; in particular they are linear, and can capture destinations.

<sup>15</sup>We said in Section 1.4 that the modal approach with ringoids would make the type system easier to extend, here is the proof.

```

go : (S  $\omega_{\text{rec}} \multimap$  T1  $\multimap$  (! $\omega_{\text{rec}}$  S)  $\otimes$  T2)  $\omega_{\text{rec}} \multimap$  S  $\omega_{\text{rec}} \multimap$  Queue (Tree T1  $\otimes$  [Tree T2])  $\multimap$  1
go f st q  $\triangleq$  case (dequeue q) of {
  Inl ()  $\mapsto$  (),
  Inr ((tree, dtree), q')  $\mapsto$  case tree of {

Listing 2.4: Syntactic sugar definitions for terms

## 2.5 Type system

$\lambda_d$  is a simply typed  $\lambda$ -calculus with unit (**1**), product ( $\otimes$ ) and sum ( $\oplus$ ) types, inspired from  $\lambda_{Ldm}$  described in Chapter 1. It also features a mode-polymorphic function arrow  $m \multimap$ . Its most distinctive features however are the destination  $[mT]$  and ampar  $S \times T$  types which we've introduced in Sections 2.2 to 2.4. Don't pay too much attention to the mode annotation on the destination type; so far it was hidden in the examples because we only considered linear destinations.

To ensure that destinations are used soundly, we need both to enforce the linearity of destinations but also to prevent destinations from escaping their scope, as discussed in Section 2.3. To that effect,  $\lambda_d$  tracks the *age* of destinations, that is how many nested scopes have been open between the current expression and the scope from which a destination originates. We'll see in Section 2.5.2 that scopes are introduced by the  $\text{upd}_\times t \text{ with } x \mapsto t'$  construct. For instance, if

Core grammar of terms:

$$\begin{aligned}
 t, u ::= & x \mid t' t \mid t \circ t' \\
 & \mid \text{case}_m t \text{ of } \{\text{Inl } x_1 \mapsto u_1, \text{Inr } x_2 \mapsto u_2\} \mid \text{case}_m t \text{ of } (x_1, x_2) \mapsto u \mid \text{case}_m t \text{ of } \text{Mod}_n x \mapsto u \\
 & \mid \text{upd}_\times t \text{ with } x \mapsto t' \mid \text{to}_\times t \mid \text{from}_\times t \mid \text{new}_\times \\
 & \mid t \triangleleft () \mid t \triangleleft \text{Inl} \mid t \triangleleft \text{Inr} \mid t \triangleleft (,) \mid t \triangleleft \text{Mod}_m \mid t \triangleleft (\lambda x_m \mapsto u) \mid t \triangleleft_\circ t' \mid t \triangleleft_\blacktriangle t'
 \end{aligned}$$

Grammar of types, modes and contexts:

$$\begin{aligned}
 \mathbf{T}, \mathbf{U}, \mathbf{S} ::= & \lfloor_n \mathbf{T} \rfloor \quad (\text{destination}) \\
 & \mid \mathbf{S} \ltimes \mathbf{T} \quad (\text{ampar}) \\
 & \mid \mathbf{1} \mid \mathbf{T}_1 \oplus \mathbf{T}_2 \mid \mathbf{T}_1 \otimes \mathbf{T}_2 \mid !_m \mathbf{T} \mid \mathbf{T}_m \multimap \mathbf{U} \\
 \Gamma ::= & \bullet \mid x :_m \mathbf{T} \mid \Gamma_1, \Gamma_2
 \end{aligned}
 \quad \left| \quad \begin{aligned}
 m, n ::= & \text{pa} \quad (\text{pair of multiplicity and age}) \\
 p ::= & \mathbf{1} \mid \omega \\
 a ::= & \uparrow^k \mid \infty \\
 \nu \triangleq & \uparrow^0 \quad \uparrow \triangleq \uparrow^1
 \end{aligned} \right.$$

Ordering on modes:

$$\text{pa} \preceq p'a' \iff p \preceq_p p' \wedge a \preceq_a a'$$

Operations on modes:

+	1	$\omega$
1	$\omega$	$\omega$
$\omega$	$\omega$	$\omega$

$\cdot$	1	$\omega$
1	1	$\omega$
$\omega$	$\omega$	$\omega$

+	$\uparrow^k$	$\infty$
$\uparrow^j$	if $k = j$ then $\uparrow^k$ else $\infty$	$\infty$
$\infty$	$\infty$	$\infty$

$\cdot$	$\uparrow^k$	$\infty$
$\uparrow^j$	$\uparrow^{k+j}$	$\infty$
$\infty$	$\infty$	$\infty$

$$\begin{aligned}
 (\text{pa}) \cdot (p'a') &\triangleq (p \cdot p')(a \cdot a') & (\text{pa}) + (p'a') &\triangleq (p + p')(a + a')
 \end{aligned}$$

Operations on typing contexts:

$$\begin{aligned}
 n \cdot \bullet &\triangleq \bullet \\
 n \cdot (x :_m \mathbf{T}, \Gamma) &\triangleq (x :_{n \cdot m} \mathbf{T}), n \cdot \Gamma
 \end{aligned}
 \quad \left| \quad \begin{aligned}
 \bullet + \Gamma &\triangleq \Gamma \\
 (x :_m \mathbf{T}, \Gamma_1) + \Gamma_2 &\triangleq x :_m \mathbf{T}, (\Gamma_1 + \Gamma_2) \quad \text{if } x \notin \Gamma_2 \\
 (x :_m \mathbf{T}, \Gamma_1) + (x :_{m'} \mathbf{T}, \Gamma_2) &\triangleq x :_{m+m'} \mathbf{T}, (\Gamma_1 + \Gamma_2)
 \end{aligned} \right.$$

Figure 2.1: Terms, types and modes of  $\lambda_d$

we have a term  $\text{upd}_\times t_1 \text{ with } x_1 \mapsto \text{upd}_\times t_2 \text{ with } x_2 \mapsto \text{upd}_\times t_3 \text{ with } x_3 \mapsto x_1$ , then we say that the innermost occurrence of  $x_1$  has age  $\uparrow^2$  because two nested  $\text{upd}_\times$  separate the definition and use site of  $x_1$ .

For  $\lambda_d$ , we take the same modal approach as for  $\lambda_{Ldm}$ , but we enrich our mode ringoid to have an *age* axis. Thanks to the algebraic nature of the modal approach, for most typing rules, we'll be able to reuse those of  $\lambda_{Ldm}$  without any modification as just the elements of the ringoid change, not the properties nor the structure of the ringoid.

The syntax of  $\lambda_d$  terms is presented in Figure 2.1, and the syntactic sugar that we used in Sections 2.2 to 2.4 is presented in Listing 2.4.

### 2.5.1 Modes and the age ringoid

Our mode ringoid (more precisely, a commutative additive semigroup  $+$  and a multiplicative monoid  $(\cdot, 1)$ , with the usual distributivity law  $n \cdot (m_1 + m_2) = n \cdot m_1 + n \cdot m_2$ , and equipped with a partial order  $\leq$ , such that  $+$  and  $\cdot$  are order-preserving) is, as promised, the product of a multiplicity ringoid, to track linearity, and an age ringoid, to prevent scope escape. The resulting compound structure is also a ringoid.

The multiplicity ringoid has elements  $1$  (linear) and  $\omega$  (unrestricted), it's the same ringoid as in [Atkey, 2018] or [Bernardy et al., 2018], and the same as described in detail in Chapter 1. The full description of the multiplicity ringoid is given again in Figure 2.1.

Ages are more interesting. We write ages as  $\uparrow^k$  (with  $k$  a natural number), for “defined  $k$  scopes ago”. We also have an age  $\infty$  for variables that don't originate from a  $\text{upd}_\times t$  with  $x \mapsto t'$  construct i.e. that aren't destinations, and can be freely used in and returned by any scope. The main role of age  $\infty$  is thus to act as a guarantee that a value doesn't contain destinations. Finally, we will write  $\nu \triangleq \uparrow^0$  (“now”) for the age of destinations that originate from the current scope; and  $\uparrow \triangleq \uparrow^1$ .

The operations or order on ages aren't the usual ones on natural numbers though. Indeed, it's crucial that  $\lambda_d$  tracks the precise age of variables, and usually, ordering on modes usually implies a form of subtyping (where a variable having mode  $n$  can be used in place where a variable with mode  $m$  is expected if  $m \leq n$ ). Here we don't want variables from two scopes ago to be used as if they were from one scope ago. The ordering reflects this with finite ages being arranged in a flat order (so  $\uparrow^1$  and  $\uparrow^2$  aren't comparable), with  $\infty$  being bigger than all of them. Multiplication of ages reflects nesting of scope, as such, (finite) ages are multiplied by adding their numerical exponents  $\uparrow^k \cdot \uparrow^j = \uparrow^{k+j}$ . In the typing rules, the most common form of scope nesting is opening a scope, which is represented by multiplying the age of existing bindings by  $\uparrow$  (that is, adding 1 to the ages seen as a natural numbers). When a same variable is shared between two subterms,  $+$  takes the least upper bound for the age order above, in other terms, the variable must be at the same age in both subterms, or have age  $\infty$  otherwise, which let it assume whichever age it needs in each subterm.

The unit of the new mode ringoid is the pair of the units from the multiplicity and age ringoids, ie.  $1\nu$ . We will usually omit the mode annotations when the mode is that unit.

Finally, as in  $\lambda_{Lm}$  and  $\lambda_{Ldm}$  from Chapter 1, operations on modes are lifted to typing contexts, still following the insights from [Ghica and Smith, 2014] (see Figure 2.1).

Anticipating on next section, let's see how *plus* works on context, modes, and especially ages. Let's type the expression  $d \blacktriangleleft x \ ; \ x$ . Most of the typing here behaves the same as  $\lambda_{Ldm}\text{-TY}$ , the only particularity is that the operator  $\blacktriangleleft$  scales the typing context of its right operand by  $\uparrow$  (which corresponds to asking it to be from the previous scope, to prevent scope escape of destinations). We have the following typing tree:

$$\frac{
 \frac{
 \frac{1\nu \leq 1\nu}{d : 1\nu \vdash d : [T]} \text{ID}_V \quad
 \frac{1\nu \leq 1\nu}{x : 1\nu \vdash x : T} \text{ID}_V
 }{d : 1\nu \vdash [T], x : \uparrow T \vdash d \blacktriangleleft x : 1} \text{[ ]E}_L \quad
 \frac{1\nu \leq 1\nu}{x : 1\nu \vdash x : T} \text{ID}_V
 }{d : 1\nu \vdash [T], x : \omega\infty T \vdash d \blacktriangleleft x \ ; \ x : T} 1E$$

At the root of the tree, with operator  $\circ$ , the typing context of the two initial branches are summed, so we have  $(d :_{1\nu} [T], x :_{1\uparrow} T) + (x :_{1\nu} T) = d :_{1\nu} [T], x :_{(1+1)(\nu+\uparrow)} T = d :_{1\nu} [T], x :_{\omega\infty} T$ . In other terms, because we need  $x$  to be of age  $\uparrow$  in the first branch, but of age  $\nu$  in the second branch —as, we recall,  $\nu = \uparrow^0$  and  $\uparrow = \uparrow^1$  are *not* comparable, so we cannot use the rule  $\lambda_d\text{-TY}/\text{ID}_V$  on a variable with mode  $1\uparrow$ — then  $x$  must be of age  $\infty$ <sup>16</sup>.

Alternatively, we can have:

$$\frac{\frac{1\nu \leq 1\nu}{d :_{1\nu} [T] \vdash d : [T]} \text{ID}_V \quad \frac{1\nu \leq \omega\infty}{x :_{\omega\infty} T \vdash x : T} \text{ID}_V}{d :_{1\nu} [T], x :_{\omega\infty} T \vdash d \triangleleft x : 1} \text{J}_L \quad \frac{1\nu \leq \omega\infty}{x :_{\omega\infty} T \vdash x : T} \text{ID}_V}{d :_{1\nu} [T], x :_{\omega\infty} T \vdash d \triangleleft x \circ x : T} \text{1E}$$

where  $x$  is given mode  $\omega\infty$  from the leaves to the root. We can make use of a variable with mode  $\omega\infty$  because we have  $1\nu \leq \omega\infty$ , which matches the premise of rule  $\lambda_d\text{-TY}/\text{ID}_V$ .

## 2.5.2 Typing rules

Core typing rules of  $\lambda_d$  are given in Figure 2.2. Rules for elimination of  $\multimap$ ,  $1$ ,  $\oplus$ ,  $\otimes$  and  $!_m$  are the same as in  $\lambda_{Ldm}$  of Chapter 1, so we won't cover them again here.

One notable difference with  $\lambda_{Ldm}$  though, is, as announced, that introduction rules for data structures, aka. data constructors for types  $1$ ,  $\oplus$ ,  $\otimes$  and  $!_m$ , are derived from elimination rules of destinations, and thus are not part of the core language. They are presented on the distinct Figure 2.3. The introduction form for functions  $\lambda_d\text{-TY}_S/\multimap\text{I}$  is also derived from elimination form  $\lambda_d\text{-TY}/[\multimap]\text{E}$  for the corresponding destinations of function, although functions are not purely “data”.

Rules  $\lambda_d\text{-TY}/\text{ID}_V$ ,  $\lambda_d\text{-TY}/\bowtie\text{NEW}$  and  $\lambda_d\text{-TY}_S/\text{1I}$ , that are the potential leaves of the typing tree, is where weakening for unrestricted variables is allowed to happen. That's why they allow to discard any typing context of the form  $\omega\nu \cdot \Gamma$ . It's very similar to what happened in  $\lambda_{Ldm}\text{-TY}/\text{ID}$  or  $\lambda_{Ldm}\text{-TY}/\text{1I}$ , except that  $\Gamma$  is scaled by  $\omega\nu$  instead of  $\omega$  now.

Rule  $\lambda_d\text{-TY}/\text{ID}_V$ , in addition to weakening, allows for coercion of the mode  $m$  of the variable used, with ordering constraint  $1\nu \leq m$  as defined in Figure 2.1. Unlike in  $\lambda_{Ldm}$ , here not all modes  $m$  are compatible with  $1\nu$ . Notably, mode coercion still doesn't allow for a finite age to be changed to another, as  $\uparrow^j$  and  $\uparrow^k$  are not comparable w.r.t.  $\leq_a$  when  $j \neq k$ . So for example we cannot use a variable with mode  $1\uparrow$  in most contexts.

For pattern-matching, with rules  $\lambda_d\text{-TY}/\oplus\text{E}$ ,  $\lambda_d\text{-TY}/\otimes\text{E}$  and  $\lambda_d\text{-TY}/!\text{E}$ , we keep the same *deep mode* approach as in  $\lambda_{Ldm}$ : **case** expressions are parametrized by a mode  $m$  by which the typing context  $\Gamma_1$  of the scrutinee is multiplied. The variables which bind the subcomponents of the scrutinee then inherit this mode.

Let's now move on to the real novelties of the typing rules for  $\lambda_d$ , that is, rules for operators acting on ampars and destinations.

<sup>16</sup>Age requirements are only there for scope-sensitive resources, that is, just destinations and the structures they are stored in. Age  $\infty$  is meant to designate non scope-sensitive resources, and consequently, is also the result of incompatible age requirements (as only non scope-sensitive resources can fit incompatible age requirements).

$\boxed{\Gamma \vdash t : \mathbb{T}}$ 

(Derived typing judgment for syntactic sugar forms)

$$\begin{array}{c}
\frac{\Gamma \vdash t : \mathbb{T} \times \mathbb{1}}{\Gamma \vdash \text{from}'_{\times} t : \mathbb{T}} \times\text{FROM}' \qquad \frac{}{\omega\nu \cdot \Gamma \vdash () : \mathbb{1}} \mathbb{1}\text{I} \qquad \frac{\Gamma_2, x : \mathbb{m}\mathbb{T} \vdash u : \mathbb{U}}{\Gamma_2 \vdash \lambda x_{\mathbb{m}} \mapsto u : \mathbb{T}_{\mathbb{m}} \multimap \mathbb{U}} \multimap\text{I} \\
\\
\frac{\Gamma_2 \vdash t : \mathbb{T}_1}{\Gamma_2 \vdash \text{Inl } t : \mathbb{T}_1 \oplus \mathbb{T}_2} \oplus\text{I}_1 \qquad \frac{\Gamma_2 \vdash t : \mathbb{T}_2}{\Gamma_2 \vdash \text{Inr } t : \mathbb{T}_1 \oplus \mathbb{T}_2} \oplus\text{I}_2 \qquad \frac{\Gamma_2 \vdash t : \mathbb{T}}{\mathbb{m} \cdot \Gamma_2 \vdash \text{Mod}_{\mathbb{m}} t : \mathbb{!}_{\mathbb{m}} \mathbb{T}} \mathbb{!}\text{I} \\
\\
\frac{\Gamma_{21} \vdash t_1 : \mathbb{T}_1 \quad \Gamma_{22} \vdash t_2 : \mathbb{T}_2}{\Gamma_{21} + \Gamma_{22} \vdash (t_1, t_2) : \mathbb{T}_1 \otimes \mathbb{T}_2} \otimes\text{I}
\end{array}$$

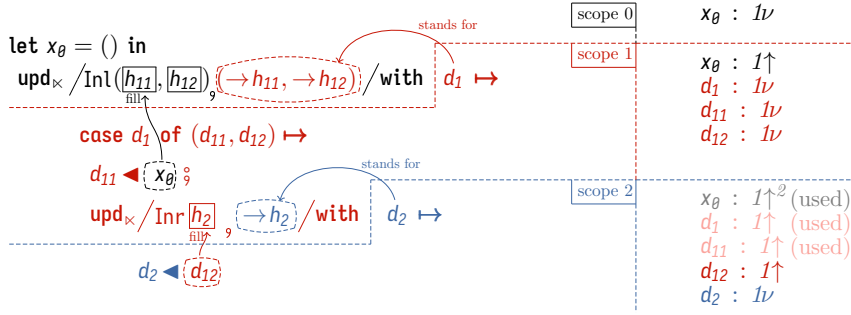

Figure 2.3: Derived typing rules for syntactic sugar ( $\lambda_d\text{-TY}_S$ )

Figure 2.4: Evolution of ages through nested scopes

**Rules for scoping** As destinations always exist in the context of a structure with holes, and must stay in that context, we need a formal notion of *scope*. Scopes are created by  $\lambda_d\text{-TY}/\times\text{UPD}$ , as destinations are only ever accessed through  $\text{upd}_\times$ . More precisely,  $\text{upd}_\times t \text{ with } x \mapsto t'$  creates a new scope which spans over  $t'$ . In that scope,  $x$  has age  $\nu$  (now), and the ages of the existing bindings in  $\Gamma_2$  are multiplied by  $\uparrow$  (i.e. we add 1 to ages seen as a numbers). That is represented by  $t'$  typing in  $\uparrow^1 \cdot \Gamma_2, x : \nu \mathbb{T}$  while the parent term  $\text{upd}_\times t \text{ with } x \mapsto t'$  types in unscaled contexts  $\Gamma_1 + \Gamma_2$ . This difference of age between  $x$ —introduced by  $\text{upd}_\times$ , containing destinations—and  $\Gamma_2$  lets us see what originates from older scopes. Specifically, distinguishing the age of destinations is crucial when typing filling primitives to avoid the pitfalls of Section 2.3.

Figure 2.4 illustrates scopes introduced by  $\text{upd}_\times$ , and how the typing rules for  $\text{upd}_\times$  and  $\blacktriangleleft$  interact. For the first time here we see ampar values  $/v_2, v_1/$ , represented as pair-like objects with a structure with holes  $v_2$  on the left, and an arbitrary structure  $v_1$  containing destinations on the right (ampar values will be formally introduced in Section 2.6.1). With  $\text{upd}_\times$  we enter a new scope where the destinations are accessible, but the structure with holes remains in the outer scope. As a result, when filling a destination with  $\lambda_d\text{-TY}/\llbracket \rrbracket_{\text{EL}}$ , for instance  $d_{11} \blacktriangleleft x_\theta$  in Figure 2.4, we type  $d_{11}$  in the new scope, while we type  $x_\theta$  in the outer scope, as it's being moved to the structure with holes on the left of the ampar, which lives in the outer scope too. This is

the opposite of the scaling that  $\mathbf{upd}_\times$  does: while  $\mathbf{upd}_\times$  creates a new scope for its body, operator  $\triangleleft$ , and similarly,  $\triangleleft_\circ$  and  $\triangleleft(\lambda x_m \mapsto u)$ , transfer their right operand to the outer scope. In other words, the right-hand side of  $\triangleleft$  or  $\triangleleft_\circ$  is an enclave for the parent scope.

When using  $\mathbf{from}'_\times$  (rule  $\lambda_d\text{-TY}_S/\times\text{FROM}'$ ), the left of an ampar is extracted to the current scope. This is the fundamental reason why the left of an ampar has to “take place” in the current scope. We know the structure is complete and can be extracted because the right-hand side is of type unit (1) and thus, no destination on the right-hand side means no hole can remain on the left.  $\mathbf{from}'_\times$  is implemented in terms of  $\mathbf{from}_\times$  in Listing 2.4 to keep the core calculus tidier (and limit the number of typing rules, evaluation contexts, etc), but it can be implemented much more efficiently in a real-world implementation.

When an ampar is eliminated with the more general  $\mathbf{from}_\times$  in rule  $\lambda_d\text{-TY}/\times\text{FROM}$  however, we extract both sides of the ampar to the current scope, even though the right-hand side is normally in a different scope. This is only safe to do because the right-hand side is required to have type  $!_{1\infty}T$ , which means it is scope-insensitive: it can’t contain any scope-controlled resource. Furthermore, it ensures that the right-hand side cannot contain destinations, so the structure has to be complete and thus is ready to be read.

In  $\lambda_d\text{-TY}/\times\text{TO}$ , on the other hand, there is no need to bother with scopes: the operator  $\mathbf{to}_\times$  wraps an already completed structure in a trivial ampar whose left side is the structure (that continues to type in the current scope), and right-hand side is unit.

The remaining operators  $\triangleleft()$ ,  $\triangleleft\text{Inl}$ ,  $\triangleleft\text{Inr}$ ,  $\triangleleft\text{Mod}_m$ ,  $\triangleleft(,)$  from rules of the form  $\lambda_d\text{-TY}/\lfloor \rfloor E$  are the other destination-filling primitives. They write a hollow constructor to the hole pointed by the destination operand, and return the potential new destinations that are created for new holes in the hollow constructor (or unit if there is none).

One specificity of  $\triangleleft_\circ$ , compared to other destination-filling primitives, is that it only accepts a destination of type  $\lfloor_{1\nu}U\rfloor$  —that is, a destination whose corresponding hole has unit mode. This restriction is deliberate. Suppose we have  $d \triangleleft_\circ(\mathbf{ampar} : u \times \lfloor_{1\nu}T\rfloor)$  where  $d : \lfloor_{\omega\nu}U\rfloor$ , meaning  $d$  refers to a hole behind a modality  $!_{\omega\nu}$ . The expression  $d \triangleleft_\circ \mathbf{ampar}$  would return the destination of type  $\lfloor_{1\nu}T\rfloor$  (such a type signature claims that the associated hole is of mode  $1\nu$ ) that constituted the right-hand side of  $\mathbf{ampar}$ . However, this destination actually points to a hole in a structure that has now been moved behind a modality  $!_{\omega\nu}$ , and must therefore only accept values of mode  $\omega\nu$ .

There is no simple way to update the mode annotations of such destinations on the fly when using  $\triangleleft_\circ$  on a destination with a modality  $m$  different than  $1\nu$ . The problem becomes even more delicate when foreign destinations —those referencing holes from others ampars— are stored on the right-hand side: their modes, on the other hand, must not be modified at all. To avoid these complexities and ensure soundness, we restrict  $\triangleleft_\circ$  to operated only on destinations whose corresponding holes have mode  $1\nu$ .

**Putting into practice** As an exercise, now that we have all the typing rules in place, we can work out the typing tree for the synthetic destination-filling operator  $\triangleleft(::)$  and the corresponding synthetic constructor  $(::)$  that we used since Section 2.2.2. We recall that  $\mathbf{List } T \triangleq 1\oplus(T\otimes(\mathbf{List } T))$ . Let’s start with the definition and then the typing tree of  $\triangleleft(::)$ :

$$\begin{aligned} \triangleleft(::) &: \lfloor_m \mathbf{List } T\rfloor \multimap (\lfloor_m T\rfloor \otimes \lfloor_m \mathbf{List } T\rfloor) \\ d \triangleleft(::) &\triangleq d \triangleleft \text{Inr } \triangleleft(,) \end{aligned}$$

Grammar extended with values:

$$\begin{aligned}
 t, u &::= \dots \mid v \\
 v &::= \boxed{h} && (\text{hole}) \\
 &\mid \rightarrow h && (\text{destination}) \\
 &\mid \textcolor{blue}{h}/v_2, v_1/ && (\text{ampar value}) \\
 &\mid () \mid \text{Inl } v \mid \text{Inr } v \mid \text{Mod}_{\textcolor{blue}{m}} v \mid (v_1, v_2) \mid \lambda_{\textcolor{blue}{v}} x_{\textcolor{blue}{m}} \mapsto u
 \end{aligned}$$

Extended grammar of typing contexts:

$$\begin{aligned}
 \Delta &::= \bullet \mid \rightarrow h :_{\textcolor{blue}{m}} \lfloor \textcolor{blue}{n} \rfloor \mathbb{T} \mid \Delta_1, \Delta_2 \\
 \Gamma &::= \bullet \mid \rightarrow h :_{\textcolor{blue}{m}} \lfloor \textcolor{blue}{n} \rfloor \mathbb{T} \mid x :_{\textcolor{blue}{m}} \mathbb{T} \mid \Gamma_1, \Gamma_2 \\
 \Theta &::= \bullet \mid \rightarrow h :_{\textcolor{blue}{m}} \lfloor \textcolor{blue}{n} \rfloor \mathbb{T} \mid \boxed{h} :_{\textcolor{blue}{n}} \mathbb{T} \mid \Theta_1, \Theta_2
 \end{aligned}$$

Operations on new typing context forms:

$$\begin{aligned}
 n' \cdot (\boxed{h} :_{\textcolor{blue}{n}} \mathbb{T}, \Theta) &\triangleq (\boxed{h} :_{n'+n} \mathbb{T}), n' \cdot \Theta \\
 n' \cdot (\rightarrow h :_{\textcolor{blue}{m}} \lfloor \textcolor{blue}{n} \rfloor \mathbb{T}, \Gamma) &\triangleq (\rightarrow h :_{n'+m} \lfloor \textcolor{blue}{n} \rfloor \mathbb{T}), n' \cdot \Gamma && \dagger \\
 (\boxed{h} :_{\textcolor{blue}{n}} \mathbb{T}, \Theta_1) + \Theta_2 &\triangleq \boxed{h} :_{\textcolor{blue}{n}} \mathbb{T}, (\Theta_1 + \Theta_2) && \text{if } h \notin \Theta_2 \\
 (\boxed{h} :_{\textcolor{blue}{n}} \mathbb{T}, \Theta_1) + (\boxed{h} :_{n'} \mathbb{T}, \Theta_2) &\triangleq \boxed{h} :_{n+n'} \mathbb{T}, (\Theta_1 + \Theta_2) \\
 (\rightarrow h :_{\textcolor{blue}{m}} \lfloor \textcolor{blue}{n} \rfloor \mathbb{T}, \Gamma_1) + \Gamma_2 &\triangleq \rightarrow h :_{\textcolor{blue}{m}} \lfloor \textcolor{blue}{n} \rfloor \mathbb{T}, (\Gamma_1 + \Gamma_2) && \text{if } h \notin \Gamma_2 && \dagger \\
 (\rightarrow h :_{\textcolor{blue}{m}} \lfloor \textcolor{blue}{n} \rfloor \mathbb{T}, \Gamma_1) + (\rightarrow h :_{m'} \lfloor \textcolor{blue}{n} \rfloor \mathbb{T}, \Gamma_2) &\triangleq \rightarrow h :_{m+m'} \lfloor \textcolor{blue}{n} \rfloor \mathbb{T}, (\Gamma_1 + \Gamma_2) && \dagger \\
 \rightarrow^{-1}(\bullet) &\triangleq \bullet \\
 \rightarrow^{-1}(\rightarrow h :_{\textcolor{blue}{m}} \lfloor \textcolor{blue}{n} \rfloor \mathbb{T}, \Delta) &\triangleq (\boxed{h} :_{\textcolor{blue}{n}} \mathbb{T}), \rightarrow^{-1}(\Delta)
 \end{aligned}$$

$\dagger$  : same rule is also true for  $\Theta$  or  $\Delta$  replacing  $\Gamma$

Figure 2.5: Runtime values, new typing context forms, and operators

But first, we need a class of runtime values (we'll often just say *values*), and their corresponding typing rules, as  $\lambda_d$  currently lacks any way to represent destinations or holes, or really any kind of value (for instance  $\text{Inl}()$  has been, so far, just syntactic sugar for a term  $\text{from}'_{\times}(\text{upd}_{\times} \text{ new}_{\times} \text{ with } d \mapsto \dots)$ ). It's a peculiarity of  $\lambda_d$  that values (in particular, data constructors) are just used during reduction; usually they are also allowed in the term syntax of functional languages as in  $\lambda_{Ldm}$ .

### 2.6.1 Runtime values and new typing context forms

The syntax of runtime values is given in Figure 2.5. It features constructors for all of our basic types, as well as functions (note that in  $\lambda_{\textcolor{blue}{v}} x_{\textcolor{blue}{m}} \mapsto u$ ,  $u$  is a term, not a value). The more interesting values are holes  $\boxed{h}$ , destinations  $\rightarrow h$ , and ampars  $\textcolor{blue}{h}/v_2, v_1/$ , which were not present

Typing values as terms:

$$\frac{\Delta \vdash_v v : \mathbb{T}}{\omega\nu \cdot \Gamma, \Delta \vdash v : \mathbb{T}} \lambda_d\text{-TY/FROMVAL}$$

$$\boxed{\Theta \vdash_v v : \mathbb{T}}$$

(Typing judgment for values)

$$\begin{array}{c} \frac{}{\boxed{h} :_{1\nu} \mathbb{T} \vdash_v \boxed{h} : \mathbb{T}} \text{ID}_H \quad \frac{1\nu \preceq m}{\rightarrow h :_m \lfloor_n \mathbb{T} \rfloor \vdash_v \rightarrow h : \lfloor_n \mathbb{T} \rfloor} \text{ID}_D \quad \frac{}{\cdot \vdash_v () : \mathbb{1}} \mathbb{1}\text{I} \\[10pt] \frac{\Delta, x :_m \mathbb{T} \vdash u : \mathbb{U}}{\Delta \vdash_v \lambda_{\nu} x \mapsto u : \mathbb{T}_m \multimap \mathbb{U}} \multimap\text{I} \quad \frac{\Theta \vdash_v v_1 : \mathbb{T}_1}{\Theta \vdash_v \text{Inl } v_1 : \mathbb{T}_1 \oplus \mathbb{T}_2} \oplus\text{I}_1 \quad \frac{\Theta \vdash_v v_2 : \mathbb{T}_2}{\Theta \vdash_v \text{Inr } v_2 : \mathbb{T}_1 \oplus \mathbb{T}_2} \oplus\text{I}_2 \\[10pt] \frac{\Theta_1 \vdash_v v_1 : \mathbb{T}_1 \quad \Theta_2 \vdash_v v_2 : \mathbb{T}_2}{\Theta_1 + \Theta_2 \vdash_v (v_1, v_2) : \mathbb{T}_1 \otimes \mathbb{T}_2} \otimes\text{I} \quad \frac{\Theta \vdash_v v' : \mathbb{T}}{n \cdot \Theta \vdash_v \text{Mod}_n v' : \lfloor_n \mathbb{T} \rfloor} \mathbb{I}\text{I} \\[10pt] \frac{1\uparrow \cdot \Delta_1, \Delta_3 \vdash_v v_1 : \mathbb{T} \quad \Delta_2, \rightarrow^{-1} \Delta_3 \vdash_v v_2 : \mathbb{U}}{\Delta_1, \Delta_2 \vdash_v \text{hnames}(\Delta_3) / v_2, v_1 / : \mathbb{U} \ltimes \mathbb{T}} \ltimes\text{I} \end{array}$$

Figure 2.6: Typing rules for runtime values ( $\lambda_d\text{-TY}_v$ )

in  $\lambda_{Ldm}$ , and that we'll describe in the rest of the section. In order for the operational semantics to use substitution, which requires substituting variables with values, we also extend the syntax of terms to include values, and we add the corresponding typing rule  $\lambda_d\text{-TY/FROMVAL}$  (at the top of Figure 2.6).

Destinations and holes are two faces of the same coin, as seen in Section 2.2.1, and we must ensure that throughout the reduction, a destination always points to a hole, and a hole is always the target of exactly one destination. Thus, the new idea of our system is to feature *hole bindings*  $\boxed{h} :_n \mathbb{T}$  and *destination bindings*  $\rightarrow h :_m \lfloor_n \mathbb{T} \rfloor$  in typing contexts in addition to the usual variable bindings  $x :_m \mathbb{T}$ . In both cases, we call  $h$  a *hole name*. We complement this by new typing context forms: we now have  $\Gamma$ ,  $\Theta$  and  $\Delta$ .  $\Gamma$  is the form of typing context used when typing terms; we allow it to contain variable bindings (as before) but also destination bindings. On the other hand, the new context form  $\Theta$  can contain both destination bindings and hole bindings, but *not a destination binding and a hole binding for the same hole name*.  $\Theta$  cannot contain variable bindings either. Finally, a typing context  $\Delta$  can only contain destination bindings.

We extend our previous context operations  $+$  and  $\cdot$  to act on the new binding forms, as described in Figure 2.5. Context addition is still very partial; for instance,  $(\boxed{h} :_n \mathbb{T}) + (\rightarrow h :_m \lfloor_{n'} \mathbb{T} \rfloor)$  is not defined, as  $h$  is present on both sides but with different binding forms.

One of the main goals of  $\lambda_d$  is to ensure that a hole value is never read. We don't distinguish values with holes from fully-defined values at the syntactic level: instead types prevent holes from being read. The type system maintains this invariant by simply not allowing any hole bindings in the context when typing terms (indeed, typing rules  $\lambda_d\text{-TY}$  from Figure 2.2 still hold, and for instance, typing contexts must be of shape  $\Gamma$ ). In fact, the only place where holes are introduced, is in typing rules for values, in Figure 2.6, and more precisely, in the left-hand side  $v_2$  of an ampar  $\# / v_2, v_1 /$  in rule  $\lambda_d\text{-TY}_V / \ltimes \text{I}$ .

Specifically, holes come from the operator  $\rightarrow^{-1}$ , which represents the hole bindings matching the specified set of destination bindings. It's a partial, pointwise operation on typing contexts  $\Delta$ , as defined in Figure 2.5. Note that  $\rightarrow^{-1}\Delta$  is undefined if any destination binding in  $\Delta$  has a mode other than  $1\nu$ .

Furthermore, in  $\lambda_d\text{-TY}_V / \ltimes \text{I}$ , the holes  $\rightarrow^{-1}\Delta_3$  and the corresponding destinations  $\Delta_3$  of the ampar are bound together and consequently removed from the ampar's typing context: this is how we ensure that, indeed, there's one destination per hole and one hole per destination. We annotate, with subscript  $\#$ , the set of hole names that an ampar  $\# / v_2, v_1 /$  bounds. That's why, in rule  $\lambda_d\text{-TY}_V / \ltimes \text{I}$ , the resulting ampar carries the set of hole names  $\text{hnames}(\Delta_3)$  (we use the operator  $\text{hnames}(\cdot)$  to denote the holes names present in a given typing context).

That being said, an ampar can also store destinations that aren't its own, from other scopes; they are represented by  $1\uparrow \cdot \Delta_1$  and  $\Delta_2$  in the respective typing contexts of  $v_1$  and  $v_2$  in  $\lambda_d\text{-TY}_V / \ltimes \text{I}$ .

Rule  $\lambda_d\text{-TY}_V / \text{ID}_H$  indicates that a hole must have mode  $1\nu$  in the typing context to be well-typed; in particular mode coercion is not allowed here, and neither is weakening. Only when a hole is behind an exponential, that mode can change to some arbitrary mode  $n$ . The mode of a hole constrains which values can be written to it, e.g. in  $\boxed{h} : n\text{T} \vdash_v \text{Mod}_n \boxed{h} : !n\text{T}$ , only a value with mode  $n$  (more precisely, a value typed in a context of the form  $n \cdot \Theta$ ) can be written to  $\boxed{h}$ .

Surprisingly, in  $\lambda_d\text{-TY}_V / \text{ID}_D$ , we see that a destination can be typed with any mode  $m$  coercible to  $1\nu$ . We did this to mimic the rule  $\lambda_d\text{-TY} / \text{ID}_V$  and make the general modal substitution lemma expressible for  $\lambda_d$ <sup>17</sup>. We formally proved however that throughout the reduction of a well-typed closed program,  $m$  will never be of multiplicity  $\omega$  or age  $\infty$  — a destination is always linear and of finite age — so mode coercion is never actually used; and we used this at our advantage to make the formal proof of the substitution lemma much easier. The other mode  $n$ , appearing in  $\lambda_d\text{-TY}_V / \text{ID}_D$ , is not the mode of the destination binding; instead it is part of the type  $[n\text{T}]$  and corresponds to the mode of values that we can write to the corresponding  $\boxed{h}$ ; so for it no coercion can take place.

**Other salient points** While values are typed in contexts  $\Theta$  allowing both destination and hole bindings, when using a value as a term in  $\lambda_d\text{-TY} / \text{FROMVAL}$ , it's only allowed to have free destinations, but no free holes (as we require a typing context of form  $\Delta$  for the value).

Notice, also, that values (used as terms, or not) can't have free variables, since contexts  $\Theta$  only contain hole and destination bindings, but no variable binding. That values are closed is a standard feature of denotational semantics or abstract machine semantics. This is true even for function values ( $\lambda_d\text{-TY}_V / \text{—}\circ \text{I}$ ), which, also is prevented from containing free holes. Since a

<sup>17</sup>Generally, in modal systems, if  $x : n\text{T}$ ,  $\Gamma \vdash u : \text{U}$  and  $\Delta \vdash v : \text{T}$  then  $m \cdot \Delta, \Gamma \vdash u[x := v] : \text{U}$  [Abel and Bernardy, 2020].

We have  $x : \omega\infty [n\text{T}] \vdash () : 1$  and  $\rightarrow h : !\nu [n\text{T}] \vdash \rightarrow h : [n\text{T}]$  so  $\omega\infty \cdot (\rightarrow h : !\nu [n\text{T}]) \vdash ()[x := \rightarrow h] : 1$  should be valid.

$$\begin{aligned}
e &::= t' [] \mid [] v \mid [] \circ u \\

\end{aligned}$$

Figure 2.7: Grammar of evaluation contexts

function's body is unevaluated, it's unclear what it'd mean for a function to contain holes; at the very least it'd complicate our system a lot, and we are unaware of any benefit supporting free holes in functions could bring.

One might wonder how we can represent a curried function  $\lambda x \mapsto \lambda y \mapsto x \text{ concat } y$  at the value level, as the inner abstraction captures the free variable  $x$ . The answer is that such a function, at value level, is encoded as  $\lambda_v x \mapsto \text{from}'_{\times}(\text{upd}_{\times} \text{ new}_{\times} \text{ with } d \mapsto d \triangleleft (\lambda y \mapsto x \text{ concat } y))$ , where the inner closure is not yet in value form. As the form  $d \triangleleft (\lambda y \mapsto x \text{ concat } y)$  is part of term syntax, it's allowed to have free variable  $x$ .

### 2.6.2 Evaluation contexts and commands

A running program is represented by a *command*  $E[t]$ , that is, a pair of an evaluation context  $E$ , and an (extended) term  $t$  under focus, as in Section 1.6.

The grammar of evaluation contexts is given in Figure 2.7. As for  $\lambda_{Ldm}$ , an evaluation context  $E$  is the composition of an arbitrary number of focusing components  $e$ . It might seem surprising that we don’t need a notion of store or state in our semantics to represent the mutation induced by filling destinations. In fact, destination filling only requires a very tame notion of state —so tame that we can simply represent writing to a hole by a substitution *on the evaluation context*, instead of using more heavy store semantics.

It’s important to note, however, that unlike in  $\lambda_{Ldm}$ , command  $E[t]$  of  $\lambda_d$  won’t always have a corresponding term. The reason is that the focusing components are all directly derived from the term syntax, except for the *open ampar* focusing component  $\text{op}_{\text{H}}/v_2, []/$  that doesn’t have a corresponding term construct. This focusing component indicates that an ampar is currently being processed by  $\text{upd}_{\kappa}$ , with its left-hand side  $v_2$  (the structure being built) being attached to the open ampar focusing component, while its right-hand side (containing destinations) is either in subsequent focusing components, or in the term under focus. Ampars being open during the evaluation of  $\text{upd}_{\kappa}$ ’s body and closed back afterwards is counterpart to the notion of scopes in typing rules.

**Typing of evaluation contexts** Evaluation contexts are typed in a context  $\Delta$  that can only contain destination bindings. The typing context  $\Delta$  of an evaluation context  $E$  is exactly the typing context that the term  $t$  has to use to form a valid  $E[t]$ . In other words, while  $\Gamma \vdash t : \mathbf{T}$  *requires* the bindings of  $\Gamma$ , judgment  $\Delta \dashv E : \mathbf{T} \rightarrow \mathbf{U}_0$  *provides* the bindings of  $\Delta$ . Typing rules for evaluation contexts, and the sole typing rule for commands, are given in Figure 2.8.

$\boxed{\Delta \dashv E : \mathbf{T} \multimap \mathbf{U}_\theta}$

(Typing judgment for commands)

$$\frac{\Delta \dashv E : \mathbf{T} \multimap \mathbf{U}_\theta \quad \Delta \vdash t : \mathbf{T}}{\vdash E[t] : \mathbf{U}_\theta} \lambda_d\text{-TY}_{\text{CMD}}$$

 Figure 2.8: Typing rules of evaluation contexts ( $\lambda_d\text{-TY}_{\text{E}}$ ) and commands ( $\lambda_d\text{-TY}_{\text{CMD}}$ )

An evaluation context has a context type  $\mathbf{T} \rightarrow \mathbf{U}_\theta$ . The meaning of  $E : \mathbf{T} \rightarrow \mathbf{U}_\theta$  is that given  $t : \mathbf{T}$ ,  $E[t]$  returns a value of type  $\mathbf{U}_\theta$ . Composing an evaluation context  $E : \mathbf{T} \rightarrow \mathbf{U}_\theta$  with a new focusing component never affects the type  $\mathbf{U}_\theta$  of the future command; only the type  $\mathbf{T}$  of the focus is altered.

All typing rules for evaluation contexts can be derived systematically from the ones for the corresponding term (except for the rule  $\lambda_d\text{-TY}_E/\ltimes\text{OP}$ , as there is no direct term equivalent to the *open ampar* focusing component). Let's take the rule  $\lambda_d\text{-TY}_E/\otimes\text{E}$  as an example:

$$\frac{\lambda_d\text{-TY}_E/\otimes\text{E} \quad \begin{array}{c} \mathbf{m} \cdot \Delta_1, \Delta_2 \vdash E : \mathbf{U} \rightarrow \mathbf{U}_\theta \\ \Delta_2, x_1 : \mathbf{m} \mathbf{T}_1, x_2 : \mathbf{m} \mathbf{T}_2 \vdash u : \mathbf{U} \end{array}}{\Delta_1 \vdash E \circ \text{case}_{\mathbf{m}} [] \text{ of } (x_1, x_2) \mapsto u : (\mathbf{T}_1 \otimes \mathbf{T}_2) \rightarrow \mathbf{U}_\theta} \quad \left| \quad \frac{\lambda_d\text{-TY}/\otimes\text{E} \quad \begin{array}{c} \Gamma_1 \vdash t : \mathbf{T}_1 \otimes \mathbf{T}_2 \\ \Gamma_2, x_1 : \mathbf{m} \mathbf{T}_1, x_2 : \mathbf{m} \mathbf{T}_2 \vdash u : \mathbf{U} \end{array}}{\mathbf{m} \cdot \Gamma_1 + \Gamma_2 \vdash \text{case}_{\mathbf{m}} t \text{ of } (x_1, x_2) \mapsto u : \mathbf{U}} \right.$$

- the typing context  $\mathbf{m} \cdot \Delta_1, \Delta_2$  in the premise for  $E$  in  $\lambda_d\text{-TY}_E/\otimes\text{E}$  corresponds to  $\mathbf{m} \cdot \Gamma_1 + \Gamma_2$  in the conclusion of  $\lambda_d\text{-TY}/\otimes\text{E}$ ;
- the typing context  $\Delta_2, x_1 : \mathbf{m} \mathbf{T}_1, x_2 : \mathbf{m} \mathbf{T}_2$  in the premise for term  $u$  in  $\lambda_d\text{-TY}_E/\otimes\text{E}$  corresponds to the typing context  $\Gamma_2, x_1 : \mathbf{m} \mathbf{T}_1, x_2 : \mathbf{m} \mathbf{T}_2$  for the same term in  $\lambda_d\text{-TY}/\otimes\text{E}$ ;
- the typing context  $\Delta_1$  in the conclusion for  $E \circ \text{case}_{\mathbf{m}} [] \text{ of } (x_1, x_2) \mapsto u$  in  $\lambda_d\text{-TY}_E/\otimes\text{E}$  corresponds to the typing context  $\Gamma_1$  in the premise for  $t$  in  $\lambda_d\text{-TY}/\otimes\text{E}$  (the term  $t$  is located where the focus  $[]$  is in  $\lambda_d\text{-TY}_E/\otimes\text{E}$ ).

We think of the typing rule for an evaluation context as a rotation of the typing rule for the associated term, where the typing contexts of one subterm and the conclusion are swapped, and the typing contexts of the other potential subterms are kept unchanged (with the difference that typing contexts for evaluation contexts are of shape  $\Delta$  instead of  $\Gamma$ ).

### 2.6.3 Reduction semantics

Now that every piece is in place, let's focus on the reduction rules of  $\lambda_d$ , displayed in Figures 2.9 and 2.10. As in Section 1.6 for  $\lambda_{Ldm}$ , focus (F suffix), unfocus (U suffix) and contraction (C suffix) rules of  $\lambda_d$  are triggered in a purely deterministic fashion. Once a subterm is a value, it cannot be focused on again.

Figure 2.9 presents all the rules that don't incur any substitution on the evaluation context.

Reduction rules for function application and pattern-matching are the same as in  $\lambda_{Ldm}$ . Reduction rules for  $\mathbf{to}_\ltimes$  are pretty straightforward: once we have a value at hand, we embed it in a trivial ampar with just unit on the right. Rules for  $\mathbf{from}_\ltimes$  are fairly symmetric: once we have an ampar with a value of the shape  $\mathbf{Mod}_{1\circ} v_1$  on the right, we can extract both the left and right side out of the ampar shell, into a normal pair.

Finally,  $\mathbf{new}_\ltimes$  has only a single rule that transforms it into the “identity” ampar object with just one hole on the left, and the corresponding destination on the right.

Rules of Figure 2.10 are all related to  $\mathbf{upd}_\ltimes$  and destination-filling operators, whose contraction rules modify the evaluation context deeply, instead of just pushing or popping a focusing component. For that, we need to introduce the special substitution  $E(h :=_{\textcolor{red}{H}} v)$  that is used to update structures under construction, that are attached to open ampar focusing components in the stack. Such a substitution is triggered when a destination  $\rightarrow h$  is filled in the term under focus,

$E[t] \longrightarrow E'[t']$	(Small-step evaluation of commands)

$\star$  : only allowed if the term that would become the new focus is not already a value

Figure 2.10: Small-step reduction of commands for  $\lambda_d$  ( $\lambda_d$ -SEM, part 2)

typically in destination-filling primitives reductions, and results in the value  $v$  being written to hole  $\boxed{h}$ . The value  $v$  may contain holes itself (e.g. when the hollow constructor  $\text{Inl } \boxed{h'+1}$  is being written to the hole  $\boxed{h}$  in  $\lambda_d\text{-SEM}/[\oplus]\text{E}_1\text{C}$ ), hence the set  $H$  tracks the potential hole names introduced by value  $v$ , and is used to update the hole name set of the corresponding (open) ampar. Proper definition of  $E(h :=_H v)$  is given at the bottom of Figure 2.9.

$\lambda_d\text{-SEM}/[\mathbf{1}]\text{EC}$  and  $\lambda_d\text{-SEM}/[\neg\circ]\text{EC}$  of Figure 2.10 do not create any new hole; they only write a value to an existing one. On the other hand, rules  $\lambda_d\text{-SEM}/[\oplus]\text{E}_1\text{C}$ ,  $\lambda_d\text{-SEM}/[\oplus]\text{E}_2\text{C}$ ,  $\lambda_d\text{-SEM}/[\mathbf{!}]\text{EC}$  and  $\lambda_d\text{-SEM}/[\otimes]\text{EC}$  all write a hollow constructor to the hole  $\boxed{h}$  that contains new holes. Thus, we need to generate fresh names for these new holes, and also return a destination for each new hole with a matching name.

The substitution  $E(h :=_H v)$  should only be performed if  $h$  is a globally unique name; otherwise we break the promise of a write-once memory model. To this effect, we allow name shadowing while an ampar is in value form (which is why  $\text{new}_\times$  is allowed to reduce to the same  $\{1\}/[\mathbf{1}], \rightarrow \mathbf{1}/$  every time), but as soon as an ampar is open (when it becomes an open ampar focusing component), it should have globally unique hole names. This restriction is enforced in rule  $\lambda_d\text{-TYE}/\ltimes\text{OP}$  by the premise  $\text{hnames}(E) \# \# \text{hnames}(\Delta_3)$ , requiring hole name sets from  $E$  and  $\Delta_3$  to be disjoint when an open ampar focusing component is created during reduction of  $\text{upd}_\times$ . Likewise, any hollow constructor written to a hole should have globally unique hole names. We assume that hole names are natural numbers for simplicity's sake.

To obtain globally fresh names, in the premises of the corresponding rules, we first set  $h' = \max(\text{hnames}(E) \cup \{h\}) + 1$  or similar definitions for  $h''$  and  $h'''$  (see at the bottom of Figure 2.10) to find a new unused name<sup>18</sup>. Then we use either the *shifted set*  $H \pm h'$  or the *conditional shift operator*  $h[H \pm h']$  as defined at the bottom of Figure 2.9 to replace all names or just a specific one with fresh unused name(s). We extend *conditional shift*  $\bullet[H \pm h']$  to arbitrary values, terms, and typing contexts in the obvious way (keeping in mind that  $\mu'/v_2, v_1/$  binds the names in  $H'$ ).

Rules  $\lambda_d\text{-SEM}/\ltimes\text{OP}$  and  $\lambda_d\text{-SEM}/\ltimes\text{CL}$  dictate how and when an ampar (a value) is converted to an open ampar (a focusing component) and vice-versa, and they make use of the shifting strategy we've just introduced. With  $\lambda_d\text{-SEM}/\ltimes\text{OP}$ , the hole names bound by the ampar gets renamed to fresh ones, and the left-hand side gets attached to the focusing component  $\text{op}_{H \pm h''}/v_2[H \pm h'']$ ,  $[\ ]/$  while the right-hand side (containing destinations) is substituted in the body of the  $\text{upd}_\times$  statement (which becomes the new term under focus). The rule  $\lambda_d\text{-SEM}/\ltimes\text{CL}$  triggers when the body of a  $\text{upd}_\times$  statement has reduced to a value. In that case, we can close the ampar, by popping the focusing component from the stack  $E$  and merging back with  $v_2$  to form an ampar value again.

In rule  $\lambda_d\text{-SEM}/[\ ]\text{E}_c\text{C}$ , we write the left-hand side  $v_2$  of an ampar value  $\mu/v_2, v_1/$  to a hole  $\boxed{h}$  that is part of a structure with holes somewhere inside  $E$ . This results in the composition of two structures with holes. Because we dissociate  $v_2$  and  $v_1$  that were previously bound together by the ampar connective ( $v_2$  is merged with another structure, while  $v_1$  becomes the new focus), their hole names are no longer bound, so we need to make them globally unique, as we do when an ampar is opened with  $\text{upd}_\times$ . This renaming is carried out by the conditional shift  $v_2[H \pm h'']$  and  $v_1[H \pm h''']$ .

<sup>18</sup>Sometimes we don't take the smallest unused name possible; it's mostly the result of using whatever made the formal proofs easier. For instance, in the formal proofs with Coq, renaming is implemented in terms of more general permutations, which make it more easily interoperable with typing contexts, represented as functions, but adds a few extra requirements to make lemma hold

**Putting into practice** Let's reuse the example from Section 2.5.2 with the synthetic  $(::)$  cons constructor, and see the reduction of expression  $() :: \text{Inl}()$ . Here,  $\text{Inl}()$  is the value form corresponding to  $\text{nil}$  (given our encoding of lists), and we also assume that  $()$  in the expression is the value form of Figure 2.5, not the syntactic constructor defined in Listing 2.4. Finally, we consider  $\text{from}'_{\kappa}$  to be a primitive (for brevity) with its contraction rule  $\lambda_d\text{-SEM}/\ltimes\text{FROM}'\text{C}$ :  $E[\text{from}'_{\kappa}(\{ \}_/v_2, ()/)] \rightarrow E[v_2]$  and trivial focus and unfocus rules.

$$\begin{aligned}

& \rightarrow ([\circ] \circ \text{from}'_{\kappa} [])[\text{op}_{\{6,7\}}/\text{Inr}([\boxed{6}], [\boxed{7}]), [\circ] \circ [\circ] \ ; \ \rightarrow 7 \triangleleft \text{Inl}())[\rightarrow 6 \triangleleft ()] && 1\text{EF} \\
& \rightarrow ([\circ] \circ \text{from}'_{\kappa} [])[\text{op}_{\{6,7\}}/\text{Inr}([\circ], [\boxed{7}]), [\circ] \circ [\circ] \ ; \ \rightarrow 7 \triangleleft \text{Inl}())[\circ] && [\ ]\text{E}_L\text{C with sub. } E\{6 := \{ \} \text{ }([\circ])\} \\
& \rightarrow ([\circ] \circ \text{from}'_{\kappa} [])[\text{op}_{\{6,7\}}/\text{Inr}([\circ], [\boxed{7}]), [\circ] \circ [\circ] \ ; \ \rightarrow 7 \triangleleft \text{Inl}())[\circ] && 1\text{EU} \\
& \rightarrow ([\circ] \circ \text{from}'_{\kappa} [])[\text{op}_{\{6,7\}}/\text{Inr}([\circ], [\boxed{7}]), [\circ] \circ [\circ] \ ; \ \rightarrow 7 \triangleleft \text{Inl}())[\circ] && 1\text{EC} \\
& \rightarrow ([\circ] \circ \text{from}'_{\kappa} [])[\text{op}_{\{6,7\}}/\text{Inr}([\circ], \text{Inl}()), [\circ] \circ [\circ]] && [\ ]\text{E}_L\text{C with sub. } E\{7 := \{ \} \text{ Inl}()\} \\
& \rightarrow ([\circ] \circ \text{from}'_{\kappa} [])[\{ \}_/\text{Inr}([\circ], \text{Inl}()), [\circ] \circ [\circ]] && \ltimes\text{CL} \\
& \rightarrow [][\text{from}'_{\kappa}(\{ \}_/\text{Inr}([\circ], \text{Inl}()), [\circ] \circ [\circ])] && \ltimes\text{FROM}'\text{U} \\
& \rightarrow [][\text{Inr}([\circ], \text{Inl}())] && \ltimes\text{FROM}'\text{C}
\end{aligned}$$

At the end of the reduction, we get the empty evaluation context with value  $\text{Inr}([\circ], \text{Inl}())$  on focus, which is the value form for the singleton list containing just unit, as expected.

We also see how, throughout the reduction, the contractions of destination-filling operations under focus will trigger global substitutions  $E(h :=_H v)$  on the evaluation context  $E$ . As said before, these substitutions are responsible for mutating the structure under construction, which is (always) attached on *open ampar* focusing component, somewhere in the evaluation context  $E$ .

### 2.6.4 Type safety

With the semantics now defined, we can state the usual type safety theorems:

**Theorem 1** (Type preservation). *If  $\vdash E[t] : \mathbf{T}$  and  $E[t] \rightarrow E'[t']$  then  $\vdash E'[t'] : \mathbf{T}$ .*

**Theorem 2** (Progress). *If  $\vdash E[t] : \mathbf{T}$  and  $\forall v, E[t] \neq [][v]$  then  $\exists E', t'. E[t] \rightarrow E'[t']$ .*

As seen in the example above, a command of the form  $[][v]$  cannot be reduced further, as it only contains a fully determined value, and no pending computation. This is the stopping point of the reduction, and any well-typed command eventually reaches this form.

## 2.7 Formal proof of type safety

We’ve proved type preservation and progress theorems with the Coq proof assistant. The artifact containing the formalization of  $\lambda_d$  and the machine-verified proofs of type-safety (Theorems 1 and 2) is available at <https://doi.org/10.5281/zenodo.14534423>.

Turning to a proof assistant was a pragmatic choice: typing context handling in  $\lambda_d$  can be quite finicky, and it was hard, without computer assistance, to make sure that we hadn’t made mistakes in our proofs. The version of  $\lambda_d$  that we’ve proved is written in Ott [Sewell et al., 2007], and the same Ott file is used as a source for the typing rules displayed in this document, making sure that we’ve proved the same system as we’re presenting; though some simplifications are applied by a script during compilation for visual clarity.

Most of the proof was done by myself with little prior experience with Coq. However the development sped up dramatically thanks to the help of my industrial advisor, who was able to use his long prior experience with Coq to introduce the good core lemmas upon which we could easily base many others.

In total the proof is about 7000 lines long, and contains nearly 500 lemmas. Many of the cases of the type preservation and progress lemmas are similar. To handle such repetitive cases, the use of a large-language-model based autocompletion system has proven quite effective, at the detriment of elegance of the proofs. For instance, we don’t have any abstract formalization of semirings: it was more expedient to brute-force the properties we needed by hand.

There are nonetheless a few points of interest in our Coq development, that we present in the next paragraphs.

**Representation of typing contexts** We represent contexts as finite-domain functions, rather than syntactic lists, as this works much better when defining sums of contexts. While there are a handful of finite function libraries in the ecosystem, we needed *finite dependent functions* (because the type of binders depends on whether we’re binding a variable name or a hole name). This did not exist, but for our limited purposes, it turned out to be feasible to roll our own (about 1000 lines of proofs). The underlying data type is actual functions: this was simpler to develop, but, as we’ll see soon, it makes equality more complex than with a bespoke data type. The definitions of the finite function and context types are provided below:

```

1 Definition Support {A B} (l : list A) (f : forall x:A, option (B x)) : Prop
2   := forall (x:A) (y:B x), f x = Some y -> List.In x l.
3
4 Record T A B := {
5   underlying :> forall x:A, option (B x);
6   supported : exists l : list A, Support l underlying;
7 }.
8
9 Inductive name : Type :=
10  | name_Var (x:var)
11  | name_DH (h:hname).
12
13 Definition binding_type_of (n : name) : Type :=
14  match n with
15  | name_Var _ => binding_var
16  | name_DH _ => binding_dh
17  end.
18
19 Inductive binding_var : Type :=
20  | binding_Var (m:mode) (T:type).
21
22 Inductive binding_dh : Type :=
23  | binding_Dest (m:mode) (T:type) (n:mode)
24  | binding_Hole (T:type) (n:mode).
25
26 Definition ctx : Type := T name binding_type_of.

```

The Support predicate indicates that a list is an over-approximation of the effective domain of our partial function. We then use the classical *constructive indefinite description* axiom to retrieve a suitable support list for a given context when needed:

```

1 (* Axiom *)
2 ClassicalEpsilon.constructive_indefinite_description
3   : forall (A : Type) (P : A -> Prop), (exists x : A, P x) -> {x : A | P x}
4
5 Definition a_support {A B} (f : T A B) : list A
6   := constructive_indefinite_description _ f.(supported).

```

We also introduce `dom ctx` as a filter over `a_support ctx` to retain only the elements in the effective domain of our partial function `ctx`.

We also need to reason about equality of typing contexts in proofs. The definition of our partial function type would naturally lend itself well to setoid equality, but unfortunately this is not supported by the inference rules we generate through Ott. As a workaround, we assume the classical *functional extensionality* and *proof irrelevance* axioms, allowing us to state that two contexts are equal as long as they assign the same binding to all variable and hole names:

```

1  (* Axioms *)
2  ProofIrrelevance.proof_irrelevance : forall (P : Prop) (p1 p2 : P), p1 = p2
3  FunctionalExtensionality.functional_extensionality_dep
4    : forall (A : Type) (B : A -> Type) (f g : forall x : A, B x),
5    (forall x : A, f x = g x) -> f = g
6
7  Lemma ext_eq' : forall {A B} (f g : T A B), f.(underlying) = g.(underlying) -> f = g.
8  Proof. intros A B [f f_supp] [g g_supp] h_ext. cbn in *. subst g. f_equal.
9    apply proof_irrelevance.
10 Qed.
11
12 Lemma ext_eq : forall {A B} (f g : T A B), (forall x, f x = g x) -> f = g.
13 Proof. intros * h_ext. apply ext_eq'.
14   apply functional_extensionality_dep.
15   assumption.
16 Qed.

```

In effect, we recover a form of extensional equality that behaves morally like setoid equality, but integrates smoothly with the infrastructure we generate through Ott.

**Partial addition of contexts** As seen in Sections 2.5.2 and 2.6.1, addition of contexts is highly partial. For example, two bindings with the same name can only be combined if they also have the same type, and we can't combine a hole binding with a destination binding for the same hole name.

Rather than encoding addition as a binary function returning an optional context—which would integrate poorly with the rules generated by Ott—we model it as a total function to contexts. Instead, to capture failure cases, we introduce a special error mode in our mode ringoid. A binding carrying this error mode signals that the whole context is considered invalid:

```

1 Definition mode : Type := option (mul * age).
2 Notation "'⊥'" := None.
3 Notation "'1v'" := (Some (pair Lin (Fin 0))).
4 Notation "'1↑'" := (Some (pair Lin (Fin 1))).
5 Notation "'1∞'" := (Some (pair Lin Inf)).
6 ...
7
8 Definition mode_plus (m1 m2 : mode) : mode :=
9 match m1, m2 with
10 | None, _ => None
11 | _, None => None
12 | Some (p1, a1), Some (p2, a2) => Some (mul_plus p1 p2, age_plus a1 a2)
13 end.
14
15 Inductive IsValid : mode -> Prop
16   := IsValidProof : forall (pa : mul * age), IsValid (Some pa).
17
18 Definition ValidOnly (G : ctx) : Prop
19   := forall (n : name) (binding : binding_type_of n), G n = Some binding -> IsValid (mode_of binding).
20 ...
21
22 Lemma ValidOnly_union_forward
23   : forall (G1 G2 : ctx), ValidOnly G1 -> ValidOnly G2 -> G1 # G2 -> ValidOnly (G1 + G2).
24 Lemma ValidOnly_union_backward
25   : forall (G1 G2 : ctx), ValidOnly (G1 + G2) -> ValidOnly G1 /\ ValidOnly G2.
26 ...

```

The cost of this approach is that most typing rules must now include explicit well-formedness conditions —such as `IsValid` and `ValidOnly`— to ensure that the input contexts do not contain any faulty bindings. Additional lemmas are required to propagate these validity conditions through context operations, using properties such as disjointness to guarantee the absence of errors in the resulting contexts.

## 2.8 Translation of prior work into $\lambda_d$ terms and types

We announced in Section 2.1 that  $\lambda_d$  subsumes existing systems. Let's see how.

**A Functional Representation of Data Structures with a Hole** Minamide's system [Minamide, 1998] introduces two primitives, `happ` and `hcomp`, as well as the hole abstraction form,  $\hat{\lambda}x \mapsto t$ , representing structures with (a) hole, where  $x$  appears exactly once in  $t$ .

The paper indicates that hole abstractions cannot have lambda abstraction, application, or case expression operating on the variable of the abstraction, but otherwise allow these constructs to appear in the body of the hole abstraction if they are operating on other variables or values.

In a well-typed, closed program, we can evaluate the body of the hole abstraction (under the  $\hat{\lambda}$ ) as far as possible, until it is almost a value except for the single occurrence of  $x$  (we know  $x$  cannot cause this reduction to be stuck, as it cannot appear in the evaluation path of an

application or case expression). Fully evaluated hole abstractions then directly translate to our ampar value form: we interpret  $\hat{\lambda}x \mapsto t$  as  $\{h\}/t[x := \boxed{h}], \rightarrow h/$ . In other terms, we take the body of the hole abstraction as the left-hand side of the ampar, with the single occurrence of the variable replaced by a hole  $\boxed{h}$ , and just use the corresponding destination  $\rightarrow h$  as the right-hand side. The type of hole abstractions,  $(T, S)\text{hfun}$ , is translated as  $S \ltimes [T]$ .

In the general case, where the hole abstraction may not be fully evaluated, we interpret it by the following sequence of operations:

- spawning a new ampar with  $\text{new}_\ltimes$ ;
- opening it with  $\text{upd}_\ltimes$ ;
- building the data constructor in which the hole variable appear by a chain of fill expressions  $d \triangleleft \dots$  or  $d \blacktriangleleft \dots$  (following the same recipe that we used to recover normal data constructors or compound constructors from destination-filling operators; see  $(::)$  at the beginning of Section 2.2.2);
- returning, as the result of the body of  $\text{upd}_\ltimes$ , the destination corresponding to the field of the data constructor in which we want the hole to be;
- other constructs, like case expressions or applications related to other variables or values are transposed untouched into the body of  $\text{upd}_\ltimes$ .

It's a bit tedious to give a formal description of the translation, but the process is nonetheless systematic, and becomes quite clear on an example, with Minamide's term on the right, and  $\lambda_d$  one on the left:

$$\begin{array}{l|l} \text{ha} : (T, \text{List } T)\text{hfun} & \text{ha}_{\lambda_d} : (\text{List } T) \ltimes [T] \\ \text{ha} \triangleq \hat{\lambda}x \mapsto \theta :: x :: (f \ 2) & \text{ha}_{\lambda_d} \triangleq \text{case } \text{upd}_\ltimes \text{ new}_\ltimes \text{ with } d \mapsto \\ & (d \triangleleft (::)) \text{ of } (d_\theta, dt) \mapsto \\ & \text{case } (dt \triangleleft (::)) \text{ of } (d_1, dt') \mapsto \\ & d_\theta \blacktriangleleft \theta \ ; \ dt' \blacktriangleleft (f \ 2) \ ; \ d_1 \end{array}$$

Once  $(f \ 2)$  has reduced to a value  $v$ , the  $\lambda_d$ 's version will be evaluated to the promised ampar form  $\#/\theta :: \boxed{h} :: v, \rightarrow h/$ .

Because destinations aren't part of [Minamide, 1998], any variable in a program from Minamide's system can be given age  $\infty$  (so mode  $1\infty$  or  $\omega\infty$  depending on whether it is linear or not), except of course the variables bound by hole abstractions.

The translation of  $\text{happ}$  and  $\text{hcomp}$  is even more direct:

$$\begin{array}{l} \text{happ} : (T, S)\text{hfun} \multimap T \multimap S \\ \text{happ}_{\lambda_d} : S \ltimes [T] \multimap T \multimap S \\ \text{happ}_{\lambda_d} \text{ ampar } x \triangleq \text{from}'_\ltimes (\text{upd}_\ltimes \text{ ampar with } d \mapsto d \blacktriangleleft x) \\ \\ \text{hcomp} : (T, S)\text{hfun} \multimap (U, T)\text{hfun} \multimap (U, S)\text{hfun} \\ \text{hcomp}_{\lambda_d} : S \ltimes [T] \multimap T \ltimes [U] \multimap S \ltimes [U] \\ \text{hcomp}_{\lambda_d} \text{ ampar}_1 \text{ ampar}_2 \triangleq \text{upd}_\ltimes \text{ ampar}_1 \text{ with } d \mapsto d \triangleleft \circ \text{ ampar}_2 \end{array}$$

With this translation we can completely express Minamide's system in  $\lambda_d$  with no loss of flexibility.

**The Functional Essence of Imperative Binary Search Trees** The portion of the work from Lorenzen, Leijen, Swierstra, and Lindley [2024] and Leijen and Lorenzen [2025] about *first-class constructor contexts* is fairly similar, in both expressiveness and presentation, to Minamide’s *hole abstractions*. A hole abstraction  $\hat{\lambda}x \mapsto t$  is written **ctx**  $t[x := \_]$ , whose body is the same as  $t$  but with an underscore  $\_$  (or a square  $\square$  in some versions of their work) in place of the named hole variable  $x$ . Similarly, **happ** is replaced by the  $++$  operator (notice the period), and **hcomp** by the  $++$  operator. Consequently, the translation for terms from [Lorenzen, Leijen, Swierstra, and Lindley, 2024; Leijen and Lorenzen, 2025] system to ours is the same as for Minamide’s system.

For types, [Lorenzen, Leijen, Swierstra, and Lindley, 2024; Leijen and Lorenzen, 2025] only define **ctx**  $\langle T \rangle$ , where the hole and the resulting structure (once the hole will be filled) are of the same type  $T$ . This translates to  $T \ltimes [T]$  in  $\lambda_d$ .

## 2.9 Implementation of $\lambda_d$ using in-place memory mutations

The formal language presented in Sections 2.5 and 2.6 is not meant to be implemented as-is. Practical implementation of most  $\lambda_d$ ’s ideas will be the focus of Chapters 3 and 4.

First,  $\lambda_d$  doesn’t have recursion, this would have obscured the formal presentation of the system. However, adding a standard form of recursion doesn’t create any complication.

Secondly, ampars are not managed linearly in  $\lambda_d$ ; only destinations are. That is to say that an ampar can be wrapped in an exponential, e.g.  $\text{Mod}_{\omega\nu} \{h\} / \emptyset :: [h]_g \rightarrow h /$  (representing a difference list  $0 :: \square$  that can be used non-linearly), and then used twice, each time in a different way:

```

case Modων {h} / ∅ :: [h]g → h / of Modων x ↦
  let x1 := x append 1 in
  let x2 := x append 2 in
  toList (x1 concat x2)
  →*      ∅ :: 1 :: ∅ :: 2 :: []

```

It may seem counter-intuitive at first, but this program is valid and safe in  $\lambda_d$ . Thanks to the renaming discipline we detailed in Section 2.6.3, every time an ampar is operated over with **upd**<sub>×</sub>, its hole names are renamed to fresh ones. One way we can implement this in practice is to allocate a fresh copy of  $x$  every time we call **upd**<sub>×</sub> on it (recall that **append** is implemented in terms of **upd**<sub>×</sub>), in a *copy-on-write* fashion. This way filling destinations is still implemented as mutation.

However, this is a long way from the efficient implementation promised in Section 2.2. Copy-on-write can be optimized using fully-in-place functional programming [Lorenzen, Leijen, and Swierstra, 2023], where, thanks to reference counting, we don’t need to perform a copy when the difference list isn’t aliased. This idea is further explored, for structure with holes specifically, in Chapter 7 of their more recent work [Leijen and Lorenzen, 2025]. But that won’t be the direction we will follow in the following development, as we don’t want to deal explicitly with reference counting.

An alternative is to refine the linear type system further in order to guarantee that ampars are unique and avoid copy-on-write altogether. We held back from doing that in the formalization of  $\lambda_d$  as, again, it obfuscates the presentation of the system without adding much in return.

To make ampars linear, we follow the recipe we developed in Section 1.8, highly inspired from [Spiwack et al., 2022; Spiwack, 2023b], and introduce a new built-in type **Token**, together with the primitive **dup**, **drop**, and **withToken**. We also switch **new**<sub>×</sub> for **new**<sub>×IP</sub>:

```

dup : Token  $\multimap$  Token $\otimes$ Token
drop : Token  $\multimap$  1
withToken : (Token  $\xrightarrow{1\infty} \multimap !_{\omega\infty} T$ )  $\multimap !_{\omega\infty} T$ 
new $_{\times IP}$  : Token  $\multimap T \times [T]$ 

```

Ampars produced by `new $_{\times IP}$`  have a linear dependency on a `Token`. If the same ampar, originally created with `new $_{\times IP}$  tok`, were to be used twice in a block  $t$ , then  $t$  would require a typing context  $\{tok :_{\omega\infty} \text{Token}\}$ , thus the block would be rejected by `withToken`. In the other hand, duplicating  $tok$  into  $tok_1$  and  $tok_2$  first, and then using each new token to create a different ampar would be linearly valid.

Now that ampars are managed linearly, we can change the allocation and renaming mechanisms:

- the hole name for a new ampar is chosen fresh right from the start (this corresponds to a new heap allocation);
- adding a new hollow constructor still requires freshness for its hole names (this corresponds to a new heap allocation too);
- Using `upd $_{\times}$`  over an ampar and filling destinations or composing two ampars using `<math>\triangleleft\circ</math>` no longer requires any renaming: we have the guarantee that all the names involved are globally fresh, and can only be used once, so it actually corresponds to an in-place memory update.

In Chapters 3 and 4, dedicated to the implementation of DPS in a functional setting, we will treat ampars as linear resources, in the same style as  $\lambda_d$  extended with `Tokens` and `new $_{\times IP}$` .

**From binary products and sums to more efficient memory forms** In  $\lambda_d$  we only have binary product in sum types. However, it's very straightforward to extend the language and implement destination-based building for n-ary sums of n-ary products, with constructors for each variant having multiple fields directly, instead of each field needing an extra indirection as in the binary sum of products `1 $\oplus$ (S $\otimes$ (T $\otimes$ U))`. In fact, we will do that as soon as next chapter. However, we still require field's values to be represented by pointers. It's a crucial for the semantics of the `<math>\triangleleft\circ</math>` operator.

## 2.10 Conclusion

$\lambda_d$  is a purely functional calculus which treats destinations as first class values that can be passed around and used in very flexible ways. It supports data structures with multiple holes, and allows both composition of data structures with holes and storing destinations in data structures that, themselves, have holes.

With  $\lambda_d$ , we can now apply some techniques and algorithms traditionally confined to imperative languages within a purely functional setting, all while preserving safety guarantees. Indeed, thanks to a linear type system augmented with a system of ages, the mutations introduced by destination use are opaque and controlled.

However, we don't anticipate that a system of ages like the one of  $\lambda_d$  will actually be used in a programming language: it's unlikely that destinations are so central to the design of a programming language that it's worth baking them so deeply in the type system. Perhaps a compiler that makes heavy use of destinations in its optimizer could use  $\lambda_d$  as a typed

intermediate representation. But, more realistically, our expectation is that  $\lambda_d$  can be used as a theoretical framework to analyze destination-passing systems: if a destination passing system can be expressed in terms of  $\lambda_d$  primitives, then it is sound.

In the chapters ahead, we aim to determine which (hopefully moderate) restrictions we have to impose on  $\lambda_d$ 's flexibility to port most of its fundamental concepts safely into a real-world functional programming language, namely, Haskell —whose type system is not as rich as  $\lambda_d$ 's one, designed on purpose for destination control.

## Chapter 3

# A first implementation of first-class destination passing in Haskell

In the previous chapter, we saw how we can build a  $\lambda$ -calculus from the ground up with first-class support for destination passing, and that still achieves memory safety. It's now time to put that into practice in an industrial-grade programming language.

The main ideas of this chapter have resulted in a publication at JFLA 2024 [Bagrel, 2024a]. Several sections have been reworked though, since the theoretical work described in Chapter 2 was still in very early stage when the article [Bagrel, 2024a] got published.

### 3.1 Linear Haskell is our implementation target

Designing an industrial-grade programming language *just* to add support for destinations would be a gigantic task, with much risk to fail. Instead, we'll base our work on an existing functional programming language. The Haskell programming language is equipped with support for linear types through its main compiler, *GHC*, since version 9.0.1 [Bernardy et al., 2018]. We kindly redirect the reader to Section 1.7 for a primer on Linear Haskell and how to use it to control resource use.

There aren't many other industrial-grade functional programming languages, and most of them don't have support for linear types, which are the first piece required to make our system safe. Thanks to recent work from Lorenzen, White, et al. [2024], OCaml will soon have support for *affinity*, but not for *linearity* (despite the aforementioned work using the term linearity). Affinity ensures that a resource can be used at most once, but does not guarantee it will be used exactly once; it may be discarded without use. This would be problematic for us, since we rely on the guarantee that destinations cannot be dropped: it ensures that when an `ampar` no longer contains destinations on the right, all holes in the corresponding structure have been filled.

From the limited set of languages available that matched our criteria, we chose Haskell to experiment with destination passing in a practical setting, aiming to implement as many ideas from  $\lambda_d$  (detailed extensively in Chapter 2) as possible. Moreover, Haskell is a *pure* functional language, which means our destination-passing API will have to be pure, with (naturally impure) memory writes safely encapsulated within it, as explained in the introduction, so that no mutation or incomplete structure can be observed by the user.

The main challenge is that Haskell, albeit incorporating linear types, doesn't have any concept of scope or age control. So we won't be able to avoid the fundamental issues presented in Section 2.3 without imposing limitations on the flexibility of the system.

## 3.2 Restricting $\lambda_d$ so that it can be made safe with just linear types

As we've seen in Section 2.3, linear types are not enough, alone, to make  $\lambda_d$  safe. We definitely need ages and scope control. In this chapter, we will take a radical decision: we will make it so that destinations can only be used to build non-linear (a.k.a. unrestricted) data structures, so that the issue of scope escape disappear completely. This also rules out the potential interaction between sibling destinations also described in Section 2.3. In exchange, we won't be able to store destinations inside data structures built using ampars.

In practice, it means that a destination can only be filled with an unrestricted value (which forbids filling a destination with another destination, as destinations are linear resources). We will use the Haskell type `data UDest t` to represent those destinations for unrestricted values, and type `data UAmpar s t` to represent these ampars where the `s` side is unrestricted.

Because there is no difference when creating the spine<sup>19</sup> of a data structures that is linear or unrestricted, our fill functions that adds a new hollow constructor to an existing structure will be exactly the same as in  $\lambda_d$ . Only the signature of fill operators acting on the leaves of data structures will change in the implementation compared to the formal definition. The mapping of operators and types between  $\lambda_d$  and DPS Haskell is given in Figure 3.1

In  $\lambda_d$ , destinations always have finite ages. As a result, we use age  $\infty$  as a marker that something doesn't contain destinations. That way, we can still enforce scope control independently of linearity. This is particularly visible in rule  $\lambda_d\text{-TY}/\text{FROM}$ , where a linear resource can be extracted from the right of an ampar as long as it has age  $\infty$ .

In DPS Haskell however, we don't have ages. So we use the fact that destinations are always linear too, and we employ the  $\omega$  multiplicity as a marker that something doesn't contain destinations. Of course, this isn't cheap; by doing so we conflate the absence of destination with non-linearity. Controlling scopes that way means we must be more conservative to preserve safety, which restrain the possibilities of a few operators.

Now, let's see how programs look like in DPS Haskell. We'll start by reimplementing examples from the previous chapter, to see how they take form in a practical setting.

## 3.3 A glimpse of DPS Haskell programming

The following subsections present three typical cases in which DPS programming brings expressiveness or performance benefits over a more traditional functional implementation. We'll start by revisiting examples from Section 2.2.

---

<sup>19</sup>The spine refers to the main chain of connected data constructors that form the overall shape of a data structure, connecting its "leaves".

Destination-filling operators:

$\lambda_d$	DPS Haskell	
$d \triangleleft ()$	fill @'() d	or d &fill @'()
$d \triangleleft \text{Inl}$	fill @'Inl d	or d &fill @'Inl
$d \triangleleft \text{Inr}$	fill @'Inr d	or d &fill @'Inr
$d \triangleleft (,)$	fill @'(,) d	or d &fill @'(,)
$d \triangleleft \text{Mod}_{\omega\infty}$	fill @'Ur d	or d &fill @'Ur
$d \triangleleft (\lambda x_m \mapsto \text{term})$	fillLeaf (\x $\rightarrow$ term) d	or d &fillLeaf (\x $\rightarrow$ term)
$d \triangleleft \circ \text{term}$	fillComp term d	or d &fillComp term
$d \triangleleft \blacktriangleleft \text{term}$	fillLeaf term d	or d &fillLeaf term

(one can see `&fill @'` as the equivalent of  $\triangleleft$  in  $\lambda_d$ , `&fillLeaf` as  $\blacktriangleleft$ , and `&fillComp` as  $\triangleleft \circ$ )

Types:

$\lambda_d$	DPS Haskell
$[\omega\infty T]$	<code>UDest t</code>
$!\omega\infty S \ltimes T$	<code>UAmpar s t</code>

Figure 3.1: Mappings between  $\lambda_d$  and DPS Haskell

### 3.3.1 Efficient difference lists

Linked lists are a staple of functional programming, but they aren't efficient for concatenation, as we've seen in Section 2.2.3, especially when the concatenation calls are nested to the left. For more efficient concatenation, we can define destination-based difference lists, which are effectively lists with a hole at the end.

This example will be the opportunity to show how DPS Haskell operates on memory. So far, with  $\lambda_d$ , we worked on a theoretical memory model with global substitutions (on the whole evaluation context) and no representation of allocations. Here, with DPS Haskell, we assume that we have a proper heap. We pay no attention right now to garbage collection / deallocation; instead we will deal with this topic in Section 3.5.1.

Following the mapping tables of Section 3.2, we know the DPS Haskell representation of difference lists is `type DList t = UAmpar [t] (UDest [t])`. As announced previously, because our difference lists are built using UAmpars, they cannot host linear resources. That's the major limitation of this first approach of DPS programming for Haskell (in particular, some examples developed in Chapter 2, like the breadth-first tree traversal, won't type as is in DPS Haskell without modifications).

As with ampars in  $\lambda_d$ , the left side of the UAmpar carries the structures being built, while the right side carries the destinations of the structure: the `UDest [t]` must be filled (with an unrestricted `[t]`) to get a readable (unrestricted) `[t]`.

The implementation of destination-backed difference lists is presented in Listing 3.1 (we recall that the  $\lambda_d$ 's version is presented in Listing 2.2). Note that Haskell uses `⚡` for typing, and `(:)` for the list *cons* constructor, which is the opposite of what these symbols mean in  $\lambda_d$ .

newUAmpar tok = UAmpar [Int] (UDest [Int])

Figure 3.2: newUAmpar tok

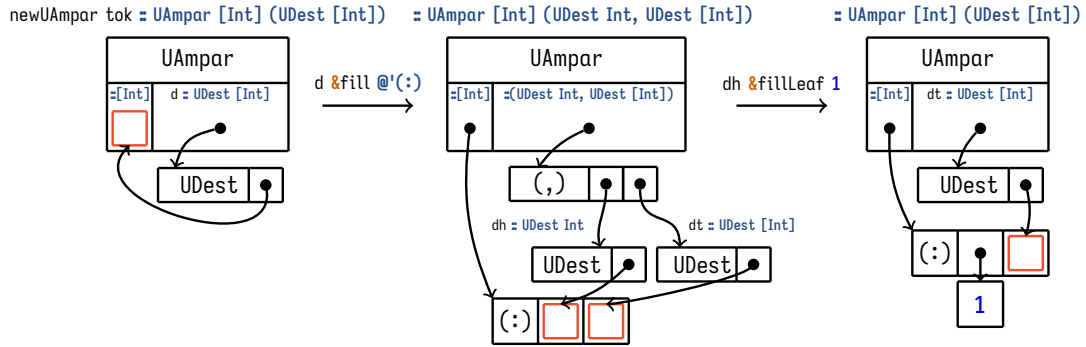

Figure 3.3: Memory behavior of append newUAmpar 1

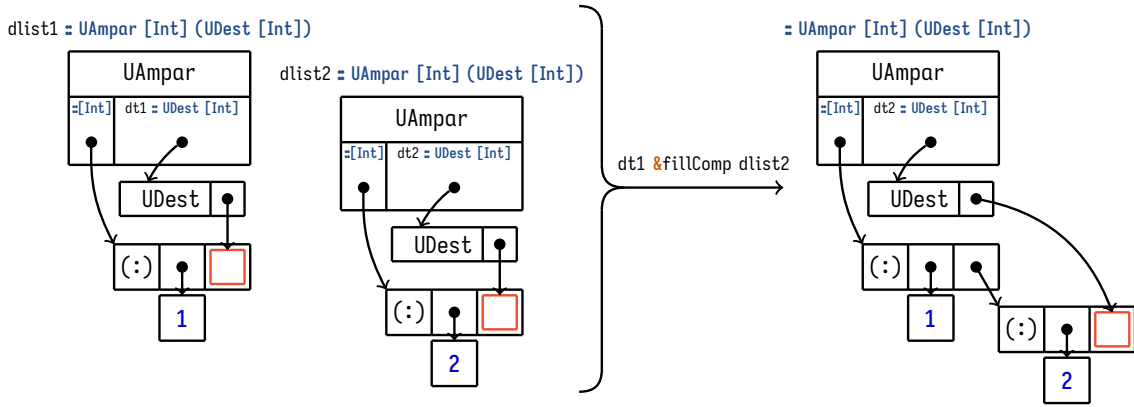

Figure 3.4: Memory behavior of concat dlist1 dlist2 (based on fillComp)

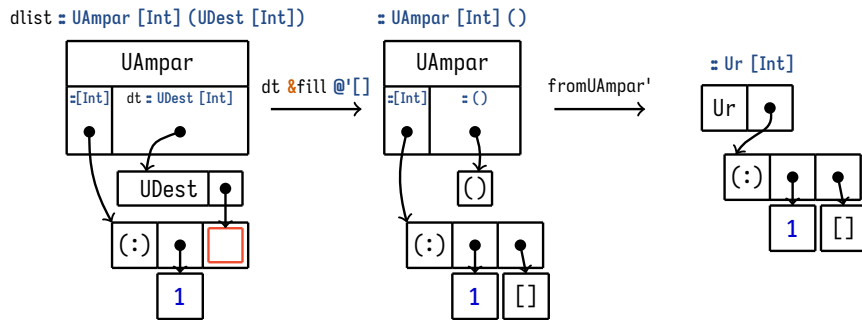

Figure 3.5: Memory behavior of toList dlist

```

1  -- we recall here the definition of list type in Haskell
2  data [t] = []          -- nil constructor
3             | (:) t [t] -- cons constructor
4
5  -- we also reuse the same linear token API as in Section 1.8
6  withToken :: (Token → Ur t) → Ur t
7
8  type DList t = UAmpar [t] (UDest [t])
9
10 newDList :: Token → DList t
11 newDList = newUAmpar @[t]
12
13 append :: DList t → t → DList t
14 dlist `append` x =
15   dlist `updWith` \d → case (d &fill @'(:)) of
16     (dh, dt) → (dh &fillLeaf x) ; dt
17
18 concat :: DList t → DList t → DList t
19 dlist1 `concat` dlist2 = dlist1 `updWith` \dt1 → (dt1 &fillComp dlist2)
20
21 toList :: DList t → Ur [t]
22 toList dlist = fromUAmpar' (dlist `updWith` \dt → dt &fill @[t])

```

Listing 3.1: Implementation of difference lists in DPS Haskell

- `newDList` is just an alias for `newUAmpar`, to linearly exchange a token for a new `UAmpar [t] (UDest [t])` —that is, exactly `DList t`. Recall that `UAmpars` are treated as linear resources now, and are created in exchange of a linear token, following the principles described in Sections 1.8 and 2.9. There is no data in this new `UAmpar` yet, it's just a hole and a destination pointing to it, as we see on Figure 3.2;
- `append` (Figure 3.3) adds an element at the tail position of a difference list. For this, it first uses `fill @'(:)` to fill the hole at the end of the list represented by `d :: UDest [t]` with a hollow `(:)` constructor that has two new holes, pointed to by `dh :: UDest t` and `dt :: UDest [t]`. Then, `fillLeaf` fills the hole represented by `dh` with the value of type `t` to append. The hole at the end of the resulting difference list is the one pointed by `dt :: UDest [t]` which hasn't been filled yet, and stays on the right side of the resulting `UAmpar`.
- `concat` (Figure 3.4) concatenates two difference lists, `dlist1` and `dlist2`. It uses `fillComp` to fill the destination `dt1` of the first difference list with the root of the second difference list `dlist2`. The resulting `UAmpar` object hence has the same root as the first list, holds the elements of both lists, and inherits the hole of the second list. Memory-wise, `concat` just writes the address of the second list into the hole of the first one.
- `toList` (Figure 3.5) completes the `UAmpar` structure by plugging a new `nil []` constructor into its hole with `fill @[t]`, and then removes the `UAmpar` wrapper as the structure is now complete, using `fromUAmpar'`. The completed list is wrapped in `Ur`, as it is allowed to be used non-linearly —it's always the case with `UAmpars`— and so that it can also escape the linear scope created by `withToken` if needed.

Linearity of UAmports, enforced by the linear token technique, is essential<sup>20</sup> to allow safe, in-place, memory updates when destination-filling operations occur, as shown in Figures 3.2 to 3.5. Otherwise, we could first complete a difference list with `let Ur l = toList dlist`, then add a new cons cell to `dlist` with `append dlist x` (actually reusing the destination inside `dlist` for the second time). This would create a hole inside `l`, although it is of type `[t]` so we would be able to pattern-match on it, and might get a segfault!

We could expect the implementation of difference list described above to be more efficient than the functional encoding (where a difference list  $x : \square$  is represented by the function  $\backslash ys \rightarrow x : ys$ ). We'll see in Section 3.6 that the prototype implementation of DPS Haskell primitives (covered in Section 3.5) cannot yet demonstrate these performance improvements.

### 3.3.2 Breadth-first tree traversal

Let's move on now to breadth-first tree traversal. We want to traverse a binary tree and update its nodes values so that they are numbered in a breadth-first order.

In Section 2.4, we took full advantage of  $\lambda_d$ 's flexibility, and implemented the breadth-first traversal using a queue to drive the processing order, as we would do in an imperative programming language. This queue would contain both input subtrees and destination to output subtrees, in breadth-first order. Furthermore, the queue was implemented efficiently using a pair of a queue and an ampar-based difference list.

Unfortunately, in DPS Haskell, destinations cannot be filled with linear elements. So an ampar-based difference list wouldn't be able to store the destinations we need to store (the one representing the output subtrees), and consequently, neither would an ampar-based efficient queue.

So we have no choice than to revert to the regular, non-ampar-based data structures of Haskell to build a suitable Hood-Melville [Hood and Melville, 1981] queue. We see here that destination passing in Haskell cannot fully replace constructors unlike in  $\lambda_d$ ; both data constructors and destination-filling primitives need to coexist<sup>21</sup>. The implementation of Hood-Melville queues is presented in Listing 3.2.

As before, for the breadth-first traversal, we'll keep a queue of pairs of a tree to be relabeled and of the destination where the relabeled result is expected, and process each of them when their turn comes. Nothing other than choice of implementation for the queue will change. The DPS Haskell implementation of breadth-first tree traversal is provided in Listing 3.3.

Except from the choice of queue implementation, and the fact that ampars must be created from `Tokens`, this implementation is very much the same as in Section 2.4. In the signature of `go` function, the linear arrow enforces the fact that every destination ever put in the queue is eventually consumed at some point, which guarantees that the output tree is complete after the function has run.

<sup>20</sup>In  $\lambda_d$  we could choose to use a smart renaming technique for hole names (morally equivalent to copy-on-write) so that ampars don't have to be managed linearly. Here, as we aim for an efficient implementation, the idea of copying ampars and updating the target of destinations on-the-go doesn't seem promising.

<sup>21</sup>Destination-based data structure building is more general than constructor-based structure building as long as we can fill destinations with linear resources, as in  $\lambda_d$ . When we add the restriction that destination can only be filled with unrestricted elements, as we do in DPS Haskell, then it is no longer more general than constructor-based structure building, and we need to conserve both building ways in the language to stay at the same level of expressiveness.

```

1 data HMQueue t = HMQueue [t] [t]
2
3 newHMQueue :: HMQueue t
4 newHMQueue = HMQueue [] []
5
6 singleton :: t → HMQueue t
7 singleton x = HMQueue [x] []
8
9 toList :: HMQueue t → [t]
10 toList (HMQueue front backRev) = front ++ reverse backRev
11
12 enqueue :: HMQueue t → t → HMQueue t
13 enqueue (HMQueue front backRev) x = HMQueue front (x : backRev)
14
15 dequeue :: HMQueue t → Maybe (t, HMQueue t)
16 dequeue (HMQueue front backRev) = case front of
17   [] → case reverse backRev of
18     [] → Nothing
19     (x : front') → Just (x, HMQueue front' [])
20   (x : front') → Just (x, HMQueue front' backRev)

```

Listing 3.2: Implementation of Hood-Melville queue in Haskell

```

18 fillLeaf :: ∀ t. t → UDest t → ()

```

Listing 3.4: Destination API for Haskell

As we will see in Section 3.6, this imperative-style implementation of breadth-first traversal in DPS Haskell, despite not using efficient queue representations such as difference lists, still shows substantial performance gains compared to the functional implementation from Gibbons et al. [2023], which we must admit, while pretty elegant, was not designed with performance as a primary focus.

## 3.4 DPS Haskell API and Design concerns

Listing 3.4 presents the pure API of DPS Haskell. This API is sufficient to implement all the examples of Section 3.3. This section explains its various parts in detail and how it compares to Chapter 2.

### 3.4.1 The UAmpar type

As with Ampars from the previous chapter, UAmpar structures, that serve as a wrapper for structures with holes, can be freely passed around and stored, but need to be completed before any reading i.e. pattern-matching can be made on them. As a result, `UAmpar s t` is defined as an opaque data type, with no public constructor.

In `UAmpar s t`, `s` stands for the type of the structure being built, and `t` is the type of what needs to be linearly consumed before the structure can be read. Eventually, when complete, the structure will be wrapped in `Ur`; this illustrates the fact that it has been made only from unrestricted elements.

The `newUAmpar` operator is the main way for a user of the API to create a new UAmpar. Its signature is equivalent to the one of `new×IP` from Section 2.9.

Also, sometimes, when programming in DPS style, we won't have a **Token** at hand, but only an existing **UAmpar**. In that case, we can piggyback on the linearity of that existing **UAmpar** (as it linearly depends, directly or indirectly, on a token) to get a new linear **Token** so that we can spawn a new **UAmpar**, or any other linear resource really. This is the goal of the `tokenBesides` function.

The operator `tokenBesides` is particularly useful when implementing efficient queues in DPS Haskell (as in Section 2.2.3):

```

1 | type DList t = UAmpar [t] (UDest [t])
2 | data EffQueue t = EffQueue [t] (DList t)
3 |
4 | newEffQueue :: Token → EffQueue t
5 | newEffQueue tok = EffQueue [] (newUAmpar @[t] tok)
6 |
7 | dequeue :: EffQueue t → Maybe (t, EffQueue t)
8 | dequeue (EffQueue front back) = case front of
9 |   [] → case (toList back) of
10 |     Ur [] → Nothing
11 |     Ur (x : xs) → Just (x, (EffQueue xs (newUAmpar @[t] tok)))
12 |   (x : xs) → Just (x, (EffQueue xs back))

```

In the second branch of the inner-most `case` in `dequeue`, when we have transformed the back difference list (from which we used to write) into the new front list (from which we will now read), we have to create a new back difference list, that is, a new `ampar`. However, we don't have a token at hand. It would be quite impractical for a function like `dequeue` to ask for a linear token to be passed; it's better if tokens are only requested when spawning a new data structure, not when operating on one. That's why `tokenBesides` comes handy: we can instead reuse the linearity requirement of the existing `UAmpar`:

```

1 | tokenBesides :: ∀ s t. UAmpar s t → (UAmpar s t, Token)
2 |
3 | dequeue :: EffQueue t → Maybe (t, EffQueue t)
4 | dequeue (EffQueue front back) = case front of
5 |   [] → case tokenBesides back of (back, tok) → case (toList back) of
6 |     Ur [] → drop tok ; Nothing
7 |     Ur (x : xs) → Just (x, (EffQueue xs (newDList tok)))
8 |   (x : xs) → Just (x, (EffQueue xs back))

```

This new version is not perfect either though. We have to create a new token before even knowing if we will need it. Indeed, we can only know if a new token is really needed when we have read the content of the old `UAmpar`, and we can only read it when it is no longer a `UAmpar`... so at that point we cannot spawn a new token any longer. So the solution is to always spawn a new token before consuming the old `UAmpar`, taking the risk that if the queue is really empty, we will have to discard the fresh token immediately (with `drop`) before returning `Nothing`. Implicit token passing, as proposed by Linear Constraints [Spiwack et al., 2022; Spiwack, 2023a], seems to really be the way forward to get rid of this kind of issues altogether.

**Getting out of an UAmpar** Same as in  $\lambda_d$ , the structure encapsulated within a UAmpar can be released in two ways: with `fromUAmpar'`, the value on the `t` side must be unit `()`, and just the complete `s` is returned, wrapped in `Ur`. With `fromUAmpar`, the type on the `t` side must be of the form `Ur t'`, and then a pair `Ur (s, t')` is returned. We recall that in  $\lambda_d$ , we had  $\text{from}'_{\times} : S \times 1 \multimap S$  and  $\text{from}_{\times} : S \times (!_{1\infty} T) \multimap (S \otimes !_{1\infty} T)$ , where the left side, when extracted from the ampar, is not wrapped in any modality.

Here in DPS Haskell, it is actually safe to wrap the structure that has been built in `Ur` because, as we've said previously, its leaves either come from non-linear sources (as `fillLeaf :: t → UDest t → ()` consumes its first argument non-linearly) or are made of 0-ary constructors added with `fill`, both of which can be used in an unrestricted fashion safely; and its spine, made of hollow constructors, can be duplicated at will.

### 3.4.2 Filling functions for destinations

The last part of the API is the one in charge of actually building the structures in a top-down fashion. To fill a hole represented by `UDest t`, three functions are available:

`fillLeaf :: ∀ t. t → UDest t → ()` uses a value of type `t` to fill the hole represented by the destination, as  $\blacktriangleleft$  from  $\lambda_d$ . However, if the destination is consumed linearly, as in  $\lambda_d$ , the value to fill the hole isn't (as indicated by the first non-linear arrow). This is key to the fact that UAmpar only host unrestricted data. Memory-wise, when `fillLeaf` is used, the address of the object of type `t` is written into the memory cell pointed to by the destination of type `UDest t` (see Figure 3.8).

`fillComp :: ∀ s t. UAmpar s t → UDest s → t` is used to plug two UAmpar objects together. The parent UAmpar isn't represented in the signature of the function, as with the similar operator  $\triangleleft$  from  $\lambda_d$ . Instead, only the hole of the parent UAmpar that will receive the address of the child UAmpar is represented in the signature of the function by `UDest s`; while `UAmpar s t` in the signature refers to the child UAmpar. A call to `fillComp` always takes place in the scope of `'updWith'` over the parent one:

```

1 | parent = UAmpar BigStruct (UDest SmallStruct, UDest OtherStruct)
2 | child = UAmpar SmallStruct (UDest Int)
3 | comp = parent `updWith` \(ds, do) → (ds & fillComp child, do)
4 |       = UAmpar BigStruct (UDest Int, UDest OtherStruct)

```

The resulting structure `comp` is morally a `BigStruct` like `parent`, that inherited the hole from the child structure (`UDest Int`) and still has its other hole (`UDest OtherStruct`) waiting to be filled. An example of memory behavior of `fillComp` in action can be seen in Figure 3.4.

Finally, `fill :: ∀ lctor t. UDest t → UDestsOf lctor t` is the generic function to fill a destination with hollow constructors. It takes a data constructor as a type parameter (`lctor`) and allocates a corresponding hollow constructor, that is, a heap object that has the same header as the specified constructor but unspecified fields. The address of the allocated hollow constructor is written in the destination that is passed to fill. An example of the memory behavior of `fill @'(:) :: UDest [t] → (UDest t, UDest [t])` is given in Figure 3.6 and the one for `fill @'[] :: UDest [t] → ()` is given in Figure 3.7.

The `fill` function also returns one destination of matching type for each of the fields of the constructor; in Haskell this is represented by `UDestsOf lctor t`. `UDestsOf` is a type family (i.e. a function from types to types) whose role is to map a constructor (lifted as a type) to the type of destina-

### 3.5. Compact Regions: a playground to implement the DPS Haskell API

Figure 3.6: Memory behavior of `fill @'(:) :: UDest [t] → (UDest t, UDest [t])`

Figure 3.7: Memory behavior of `fill @[ ] :: UDest [t] → ()`

Figure 3.8: Memory behavior of `fillLeaf :: t → UDest [t] → ()`

tions for its fields. For example, `UDestsOf '[] [t] = ()` and `UDestsOf '(:) [t] = (UDest t, UDest [t])`. More generally, the `UDestsOf` typeclass reflects the duality between the types of fields of a constructor and the ones of destinations for a hollow constructor, as first evoked in Section 2.2.1.

## 3.5 Compact Regions: a playground to implement the DPS Haskell API

Having incomplete structures in the memory inherently introduces a lot of tension with both the garbage collector and compiler. Indeed, the garbage collector of GHC assumes that every heap object it traverses is well-formed, whereas `UAmper` structures are absolutely ill-formed: they contain uninitialized pointers, which the GC should absolutely not follow. Also, the compiler and GC can make some optimizations because they assume that every object is immutable, while DPS programming breaks that guarantee by mutating constructors after they have been allocated (albeit only one update can happen). Consequently, we looked for an alternative memory management scheme, mostly independent from the garbage collector, that would let us implement the DPS Haskell API without having to change the garbage collector internals or the memory representation used by GHC.

### 3.5.1 Compact Regions

*Compact regions* from Yang et al. [2015] are special memory *arenas* for Haskell. A compact region represents a memory area in the Haskell heap that is almost fully independent from the GC and the rest of the garbage-collected heap. For the GC, each compact region is seen as a single heap object with a single lifetime. The GC can efficiently check whether there is at least one pointer in the garbage-collected heap that points into the region, and while this is the case, the region is kept alive. When this condition is no longer matched, the whole region is discarded. The result is that the GC won't traverse any node from the region: it is treated as one opaque block (even though it is actually implemented as a chain of blocks of the same size, this doesn't change the principle). Also, compact regions are immobile in memory; the GC won't move them, so a destination to a hole in the compact region can just be implemented as a raw pointer (type `Addr#` in Haskell): `data UDest r t = UDest Addr#`, as we have the guarantee that the `UAmpar` containing the pointed hole won't move.

By using compact regions to implement DPS programming, we completely elude the concerns of tension between the garbage collector and `UAmpar` structures that we just mentioned above. Conversely, our destination-passing API also provides a new and powerful way to use compact regions.

In exchange for this implementation decision, we get two extra restrictions. First, every structure in a region must be in a fully-evaluated form. This is contrasting with the usual Haskell evaluation scheme, where everything is lazy by default. Consequently, as regions are strict, any heap object that is copied to a region is first forced into normal form (i.e. it is being fully evaluated). This might not always be a win, sometimes laziness is preferable for better performance.

Secondly, data in a region cannot contain pointers to the garbage-collected heap, or pointers to other regions: it must be self-contained. This forces us to slightly modify the API, to add a phantom type parameter `r` that tags each object with the identifier of the region it belongs to so that our API remains memory-safe, without runtime checks. There are two related consequences: first, when a value from the garbage-collected heap is used as an argument to `fillLeaf`, it has to be fully evaluated and copied into the region instead of making just a pointer update; and secondly, `fillComp` can only plug together two `UAmpars` that come from the same region.

A typeclass `Region r` is also needed to carry around the details about a region that are required for the implementation. This typeclass has a single method `reflect`, not available to the user, that returns the `RegionInfo` structure associated to identifier `r`.

The `inRegion` function is the new addition to the modified API presented in Listing 3.5. It receives an expression of arbitrary type in which `r` must be a free type variable. Internally, when used, it spawns a new compact region and a rigid type variable `r` (behaving like a fresh, concrete, opaque type) and uses the `reflection` library to provide an instance of `Region r` on-the-fly that links `r` and the `RegionInfo` for the new region (through the `reflect` function), and then substitute `r` with `r` when evaluating the body of `inRegion`, so that any call to `reflect @r` becomes `reflect @r` and returns the right `RegionInfo`. Actually, `inRegion` is a form of scope function (although this time, it isn't linear).

### 3.5. Compact Regions: a playground to implement the DPS Haskell API

```
1 data Token
2 dup :: Token -> (Token, Token)
3 drop :: Token -> ()
4 withToken :: ∀ t. (Token -> Ur t) -> Ur t
5
6 type Region r :: Constraint
7 inRegion :: ∀ t. (∀ r. Region r => t) -> t
8
9 data UAmpar r s t
10 newUAmpar :: ∀ r s. Region r => Token -> UAmpar s (UDest r s)
11 tokenBesides :: ∀ r s t. Region r => UAmpar r s t -> (UAmpar r s t, Token)
12 toUAmpar :: ∀ r s. Region r => Token -> s -> UAmpar r s ()
13 fromUAmpar :: ∀ r s t. Region r => UAmpar r s (Ur t) -> Ur (s, t)
14 fromUAmpar' :: ∀ r s. Region r => UAmpar r s () -> Ur s
15 updWith :: ∀ r s t u. Region r => UAmpar r s t -> (t -> u) -> UAmpar r s u
16
17 data UDest r t
18 type family UDestsOf lCtor r t -- returns dests associated to fields of constructor
19 fill :: ∀ lCtor r t. Region r => UDest r t -> UDestsOf lCtor r t
20 fillComp :: ∀ r s t. Region r => UAmpar r s t -> UDest r s -> t
21 fillLeaf :: ∀ r t. Region r => t -> UDest r t -> ()
```

Listing 3.5: Destination API using compact regions

#### 3.5.2 DPS programming in Compact regions: Deserializing, lifetime, and garbage collection

We will now study an example, related to implementation concerns, for which DPS programming really shines (and for which compact regions are a really nice fit).

In client-server applications, the following pattern is very frequent: the server receives a request from a client with a serialized payload, the server then deserializes the payload, runs some code, and respond to the request. Most often, the deserialized payload is kept alive for the entirety of the request handling. In a garbage collected language, there's a real cost to this: the garbage collector (GC) will traverse the deserialized payload again and again, although we know that all its internal pointers are live for the duration of the request.

Instead, we'd rather consider the deserialized payload as a single heap object, which doesn't need to be traversed, and can be freed as a block. Compact regions are, in fact, a very suitable tool for this job, as the GC never follows pointers into a compact region and consider each region as having the same lifetime for all its contents.

If we use compact regions as-is, with the API provided with GHC, we would first deserialize the payload normally, in the GC heap, then copy it into a compact region and then only keep a reference to the copy. That way, internal pointers of the region copy will never be followed by the GC, and that copy will be collected as a whole later on, whereas the original one in the GC heap will be collected immediately.

```

1 | parseSList :: ByteString → Int → [SExpr] → Either Error SExpr
2 | parseSList bs i acc = case bs !? i of
3 |   Nothing → Left (UnexpectedEOFSList i)
4 |   Just x → if
5 |     | x == ')' → Right (SList i (reverse acc))
6 |     | isSpace x → parseSList bs (i + 1) acc
7 |     | otherwise → case parseSExpr bs i of
8 |       Left err → Left err
9 |       Right child → parseSList bs (endPos child + 1) (child : acc)

```

Listing 3.6: Implementation of the S-expression parser without destinations

However, we are still allocating two copies of the deserialized payload. This is wasteful, it would be much better to allocate directly in the region. Fortunately, with our implementation of DPS Haskell with compact regions, we now have a much better way to allocate and build structures directly into these compact regions!

Let’s see how using destinations and compact regions for a parser of S-expressions (representing our request payload) can lead to greater performance. S-expressions are parenthesized lists whose elements are separated by spaces. These elements can be of several types: int, string, symbol (a textual token with no quotes around it), or a list of other S-expressions.

Parsing an S-expression can be done naively with mutually recursive functions:

- `parseSExpr` scans the next character, and either dispatches to `parseSList` if it encounters an opening parenthesis, or to `parseSString` if it encounters an opening quote, or eventually parses the string into a number or symbol;
- `parseSList` calls `parseSExpr` to parse the next token, and then calls itself again until reaching a closing parenthesis, accumulating the parsed elements along the way.

Only the implementation of `parseSList` will be presented here as it is enough for our purpose, but the full implementation of both the naive and destination-based versions of the whole parser can be found in `src/Compact/Pure/SExpr.hs` of [Bagrel, 2023b].

The implementation presented in Listing 3.6 is quite standard: the accumulator `acc` collects the nodes that are returned by `parseSExpr` in the reverse order (because it’s the natural building order for a linked list without destinations). When the end of the list is reached (line 5), the accumulator is reversed, wrapped in the `SList` constructor, and returned. We also store, in the parsed result, the index `i` corresponding to the end position of the structure in the input string.

We will see that destinations can bring very significative performance gains with only very little stylistic changes in the code. Accumulators of tail-recursive functions just have to be changed into destinations. Instead of writing elements into a list that will be reversed at the end as we did before, the program in the destination style will directly write the elements into their final location and in the right order!

Code for `parseSListDPS` is presented in Listing 3.7. Let’s see what changed compared to the naive implementation:

- even for error cases, we are forced to consume the destination that we receive as an argument (to stay linear), hence we write some sensible default data to it (see line 3);

### 3.5. Compact Regions: a playground to implement the DPS Haskell API

- the `SExpr` value resulting from `parseSExprDps` is not collected by `parseSListDPS` but instead written directly into its final location by `parseSExprDps` through the passing and filling of destination `dh` (see line 9);
- adding an element of type `SExpr` to the accumulator `[SExpr]` is replaced with writing a new cons cell with fill `@(:)` into the hole represented by the `UDest [SExpr]`, writing an element to the new *head* destination, and then doing a recursive call with the new *tail* destination passed as an argument (which has type `UDest [SExpr]` again);
- instead of reversing and returning the accumulator at the end of the processing, it is enough to complete the list by writing a nil element to the tail destination (with fill `@[]`, see line 5), as the list has been built in a top-down approach;
- ultimately, DPS functions just return the offset of the next character to read instead of returning a parsed value (as the parsed value is written directly into the destination received as a parameter).

Thanks to that new implementation which is barely longer (in terms of lines of code) than the naive one, the program runs almost twice as fast, mostly because garbage-collection time goes to almost zero. The detailed benchmark is available in Section 3.6.

We see here that compact regions and destination-passing style are quite symbiotic; compact regions makes the DPS Haskell API easy to implement, and destination-passing style makes compact regions more efficient and flexible to use.

#### 3.5.3 Memory representation of UAmpar objects in Compact Regions

As we detailed in Sections 2.6.1 and 3.3.1, we want `UAmpar r s t` to contains a value of type `s` and one of type `t`, and let the value of type `s` free when the one of type `t` has been fully consumed (or linearly transformed into `Ur t'`).

We also know that `newUAmpar` returns an `UAmpar r s (UDest s)`: there is nothing more here than an empty memory cell that will host the root of the future structure of type `s`, which the associated destination of type `UDest s` points to, as presented in Figure 3.2. As we said earlier, whatever goes in the destination is exactly what will be retrieved in the `s` side.

```

1 | parseSListDPS :: ByteString → Int → UDest [SExpr] → Either Error Int
2 | parseSListDPS bs i d = case bs !? i of
3 |   Nothing → d &fill @'[] ; Left (UnexpectedEOFSList i)
4 |   Just x → if
5 |     | x == ')' → d &fill @'[] ; Right i
6 |     | isSpace x → parseSListDPS bs (i + 1) d
7 |     | otherwise →
8 |       case d &fill @'(:) of
9 |         (dh, dt) → case parseSExprDps bs i dh of
10 |           Left err → dt &fill @'[] ; Left err
11 |           Right endPos → parseSListDPS bs (endPos + 1) dt

```

Listing 3.7: Implementation of the S-expression parser with destinations

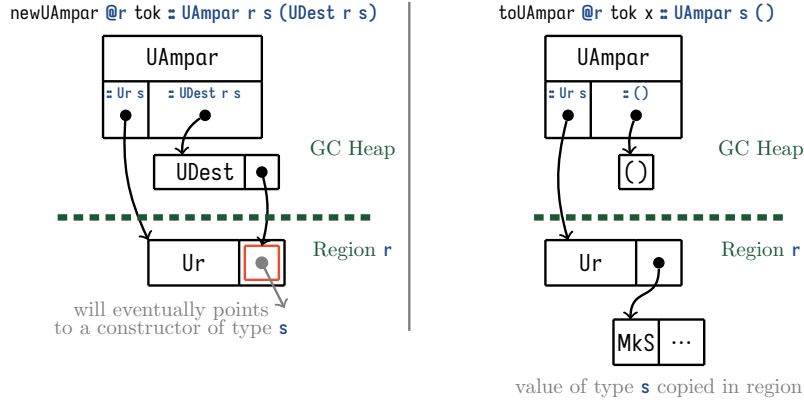

Figure 3.9: Representation of UAmpars in the compact region implementation, using `Ur` (not chosen)

The naive and most direct idea is to represent `UAmpar r s t` in memory as a pair-like constructor with one field of type `s` and one of type `t`, with the first field being there to host the root of the structure being built (as in Figure 3.2). However, the root hole, that will later host the structure of type `s`, might contain garbage data, so the GC must be prevented to read it and follow uninitialized pointers (otherwise we risk a segmentation fault). In our compact region implementation, we can prevent this issue by having the root hole live inside the compact region (so that the GC doesn't look into it). But we also want the `UAmpar` constructor to live in the garbage-collected heap so that it can sometimes be optimized away by the compiler, and always deallocated as soon as possible. These two requirements are, apparently, incompatible, as the root hole corresponds to the first field of the `UAmpar` constructor in this representation.

Given that UAmpars hold unrestricted data, one potential workaround is to represent `UAmpar r s t` in memory as a constructor with one field of type `Ur s` and one of type `t` (instead of one of type `s` and one of type `t` previously). It means we need an intermediary `Ur` constructor between the `UAmpar` wrapper and the structure of type `s` being built, and we can decide to allocate this `Ur` constructor inside the region, with its field of type `s`, also inside the region, serving as the root hole. With this approach, illustrated in Figure 3.9, we have a root hole that won't be read by the GC, while the `UAmpar` wrapper can live in the GC heap without issues and be discarded as soon as possible, as we wanted! We also get a very efficient implementation of `fromUAmpar'`, as the first field of a completed `UAmpar` is directly what `fromUAmpar'` should return (it doesn't help for `fromUAmpar` though). The downside is that every `UAmpar` will now allocate a few words in the region (to host the `Ur` constructor<sup>22</sup>) that won't be collected by the GC for a long time even if the parent `UAmpar` is collected. In particular, this makes `toUAmpar` quite inefficient memory-wise, as it will have to allocate a `Ur` wrapper in the region that is useless for already complete structures (because already complete structures don't need to have a root hole living in the compact region, as they don't have holes at all).

Another option, that we decided to go for in our real implementation, is to allocate an object inside the compact region to host the root hole of the structure *only* for truly incomplete structures created with `newUAmpar`. For already complete structures that are turned into an

<sup>22</sup>One might ask why `Ur` can't be a zero-cost `newtype` wrapper. First, if `Ur` were a `newtype`, it wouldn't work for what we are trying to achieve here, as we are relying on the fact that it creates an indirection in memory. Secondly, and more importantly, there are semantics motivations, detailed in [Spiwack, 2024].

### 3.5. Compact Regions: a playground to implement the DPS Haskell API

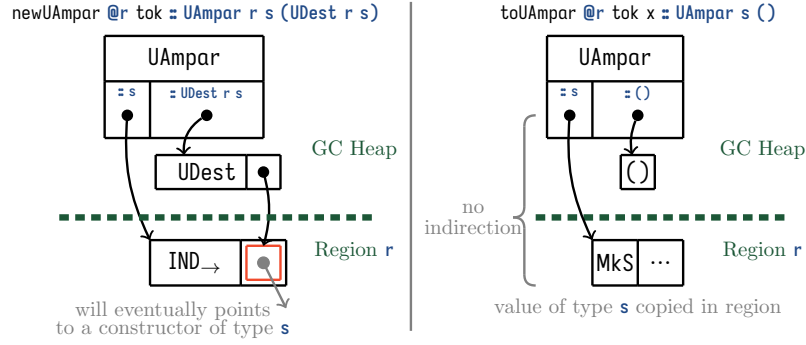

Figure 3.10: Chosen representation for `UAmpars` in the compact region implementation, using indirections

`UAmpar` with `toUAmpar`, we skip this allocation; but we preserve the same underlying types for the fields of the `UAmpar` in both cases (`newUAmpar` and `toUAmpar`). This is made possible by the use of the special indirection object (`stg_IND` in GHC codebase) in the `UAmpar` returned by `newUAmpar`. A `stg_IND` object is a kind of one-field constructor that is considered to have type `s` although its field also has type `s`. We illustrate this in Figure 3.10:

- in the pair-like structure returned by `newUAmpar`, the `s` side points to an indirection object, which is allocated in the region, and serves as the root hole for the incomplete structure (because it is in the compact region, the GC won't follow garbage pointers that it might contain at the moment);
- in the pair-like structure returned by `toUAmpar`, the `s` side directly points to the object of type `s` that has been copied to the region, without indirection.

Compared to the previous solution, this one is more efficient when using `toUAmpar` (as no long-lived garbage is produced), but does no longer give efficiency benefits for `fromUAmpar`' (as we no longer produce an `Ur` object). This is the solution we arbitrarily chose to implement in the original artifact [Bagrel, 2023b], but it could be worth comparing and benchmarking it with the one based on `Ur` indirection in a variety of real-world use-cases.

In the end, in [Bagrel, 2023b], we have the following private definitions<sup>23</sup> for our API types:

```

1 | data Token = Token -- same representation as ()
2 | data UAmpar r s t = UAmpar s t -- same representation as (s, t),
3 |                               -- with sometimes an indirection on the s field
4 | data UDest r t = UDest Addr# -- boxed Addr#, same representation as Ptr t

```

#### 3.5.4 Deriving fill for all constructors with Generics

In  $\lambda_d$ , it was quite easy to have a dedicated destination-filling function for each corresponding data constructor. Indeed, we only had to account for a finite number of them (one for unit, two for sums, one for pair, and one for exponential; with the one for function being quite optional).

<sup>23</sup>In the sense that they are opaque for the consumer of the API.

In Haskell however, we want to be able to do destination passing with arbitrary data types, even user-defined ones, so it wouldn't be feasible to implement, manually, one filling function per possible data constructor. So instead, we have to generalize all filling functions into a polymorphic fill function that is able to work for any data constructor.

To this extend, we create a typeclass `Fill lCtor t`, and we define `fill` as the only method of this class. Having such a typeclass let us tie the behaviour of `fill` to the type parameter `lCtor`. The idea is that `lCtor` represents the type-level name of the data constructor we want to use `fill` with. The syntax at call site is of the form `fill @'Ctor`: we lift the constructor `Ctor` into a type-level name with the `'` operator, then make a type application with `@`. We recall that the `fill` function should plug a new hollow constructor of the specified variant into the hole of a structure whose corresponding destination is received as an argument.

Let's now see how we can use the type-level name of the constructor `lCtor` and its base type `t` to obtain all the information we need to write the concrete implementation of the corresponding fill function. The first thing we need to know is the shape of the constructor and more precisely the number and types of its fields, as every data constructor for a linked data type can be seen as a n-ary product constructor. So we will leverage `GHC.Generics` to find the required information.

`GHC.Generics` is a built-in Haskell library that provides compile-time inspection of a type metadata through the `Generic` typeclass: list of constructors, their fields, memory representation, etc. And that typeclass can be derived automatically for (almost) any type! Here's, for example, the `Generic` representation of `Maybe t`:

```
1 | repl> :k! Rep (Maybe a) () -- display the Generic representation of Maybe a
2 | M1 D (MetaData "Maybe" "GHC.Maybe" "base" False) (
3 |   M1 C (MetaCons "Nothing" PrefixI False) U1
4 |   :+: M1 C (MetaCons "Just" PrefixI False) (M1 S [...] (K1 R t)))
```

We see that there are two different constructors (indicated by `M1 C ...` lines): `Nothing` has zero fields (indicated by `U1`) and `Just` has one field of type `t` (indicated by `K1 R t`).

As illustrated with the example above, the generic representation of a type contains most of what we want to know about its constructors. So, with type-level programming techniques<sup>24</sup>, in particular with type families, we can extract the parts of this generic representation that are relevant to us (as type-level expressions), and refer to them in the head of our typeclass' instances, to have several specialized implementation of `fill`. For instance, in [Bagrel, 2023b], we have one specialized implementation of `fill` for every possible number of fields in `lCtor`, from 0 to 7<sup>25</sup>. The main reason is that `fill` should return a tuple containing as many new destinations as there are fields in the chosen constructor, and at the moment, there is no way to abstract over the length of a tuple in Haskell, so we need to harcode each possible case.

The resolution of the `UDestsOf lCtor t` type family into a concrete tuple type of destinations is made similarly, by type-level expressions based on the generic representation of the base type `t` which `lCtor` belongs to.

At this point we still miss a major ingredient though: the internal Haskell machinery to allocate the proper hollow constructor object in the compact region.

<sup>24</sup>see `src/Compact/Pure/Internal.hs:418` in [Bagrel, 2023b]

<sup>25</sup>We could go higher, 7 is just an arbitrary limit for the number of fields that is rather common in standard Haskell libraries.

### 3.5.5 Changes to GHC internals and its RTS

We will see here how to allocate a hollow constructor, that is, a hollow heap object for a given constructor, but let's first take a detour to give more context about the internals of the compiler.

Haskell's runtime system (RTS) is written in a mix of C and C++ [Ramsey, Jones, and Lindig, 2005]. The RTS has many roles, among which managing threads, organizing garbage collection or managing compact regions. It also defines various primitive operations, named *external primops*, that expose the RTS capabilities as normal functions that can be used in Haskell code. Despite all its responsibilities, however, the RTS is not responsible for the allocation of normal constructors (built in the garbage-collected heap). One reason is that it doesn't have all the information needed to build a constructor heap object, namely, the info table associated to the constructor.

In Haskell, a heap object is a piece of data in memory, that corresponds to a given instance of a data constructor, or a (partially-applied) function. The info table is what defines both the layout and behavior of a heap object. All heap objects representing a same data constructor (let's say `Just`) have the same info table, which acts as the identity card for this constructor, even when the associated types are different (e.g. `Just x :: Maybe Int` and `Just y :: Maybe Bool` shares the same info table). In the compilation process, during code generation, all instances of the `Just` constructor will hold the label `Just_con_info`, that is later resolved by the linker into an actual pointer to the shared info table, that all corresponding heap objects for this constructor will carry.

On the other hand, the RTS is a static piece of code that is compiled once when GHC is built, and is then linked into every executable built by GHC. Only when a program is launched does the RTS run (to oversee the program execution), so the RTS has no direct way to access the information that had been emitted during the compilation of the program. In particular, it has no way to inspect the info table labels have long been replaced by actual pointers (which are indistinguishable in memory from any other data). But on the other hand, the RTS is the one which knows how to allocate space inside a compact region for our new hollow constructor.

As a result, we need a way to pass information, or more precisely, the info table pointer, from compile time to the runtime. Consequently, we manage the creation of a new hollow constructor in a compact region through two new primitives:

- one *internal primop* which resolves, at compile time, a data constructor into the (static) value representing its info table pointer.
- one *external primop*, in the RTS, which allocates space inside a compact region for a hollow constructor, and which sets the info table pointer of the hollow constructor to a value received as an argument, that the developer can provide using the internal primop.

All the alterations to GHC that will be showed here are available in full form in [Bagrel, 2023a].

#### Internal primop: obtain the info table pointer of a constructor as a static value

Internal primops are macros that are transformed at compile time into C++ code. So for our new internal primop, in charge of obtaining the info table label (later resolved into a pointer) of a constructor, we must indicate our choice of constructor as a type-level argument so that it can be inspected at compile-time (as, of course, term-level values cannot be inspected easily at compile

time). For that, we use the *tick* operator `'` in front of the constructor name, which promotes an object from the term-level namespace (in which data constructors live) to type-level, to be used where a type would normally be expected<sup>26</sup>.

Now, we need the internal primop to inspect the type parameter representing our choice of constructor. Usually, in Haskell, we use a parameter of type `Proxy t` (the unit type with a phantom type parameter `t`) as a carrier for a type-level input that we want to pass to a function. Unfortunately, primops are special functions, and due to a quirk of the compiler, they no longer have access to the type of their arguments at the stage in which they are resolved, so designing our primop with a `Proxy lCtor` parameter wouldn't let it read the supplied `lCtor`. However primops can —surprisingly— access their return type. Consequently, we design a custom return type `InfoPtrPlaceholder#` for our primop that carries the output value of the primop (that is to say, an info table pointer); but we also add a phantom type parameter `lCtor` to `InfoPtrPlaceholder#` that has no relation to the underlying value, but just serves as a carrier for our type-level input representing the chosen constructor!

The concrete implementation is presented briefly in Listing 3.8 (we omit the roughly one hundred lines of boilerplate code scattered across other parts of the GHC codebase that handle primop registration, interface declaration, etc.). This implementation goes a bit further than what we just described above, as `reifyInfoPtr#` can obtain the info table pointer of data constructors (as announced), but also the info table pointer of special compiler objects like the indirection object we used in Section 3.5.3. The primop pattern-matches on the type `resTy` of its return value (which should be of the form of the form `InfoPtrPlaceholder# lCtorOrSym`). In the case it reads a lifted data constructor (which is the most common case), it resolves the primop call into the label `<ctor>_con_info` which corresponds to the info table pointer of that constructor. In the case `lCtorOrSym` is a symbol (that is, a type-level string literal), it resolves the primop call into the label `stg_<sym>` (e.g. to allocate a `stg_IND` object, as we just mentioned). The returned `InfoPtrPlaceholder# lCtorOrSym` can later be converted back to an `Addr#` using the `unsafeCoerceAddr` function, which despite the name, is not a very unsafe coercion as it can only be used on two types sharing the same underlying representation.

**External primop: allocate a hollow constructor in a region** Our external primop, as part of the RTS, is directly written in C--. Its implementation is presented in Listing 3.9, under the name `stg_compactAddHollowzh`; but in Haskell code we access it through the name `compactAddHollow#`. The primop consists mostly in a glorified call to the `ALLOCATE` macro defined in the `Compact.cmm` file, which tries to do a pointer-bumping allocation in the current block of the compact region if there is enough space, and otherwise add a new block to the region. Then, it takes the info table pointer of the constructor to allocate, received as its second parameter `W_info` (as it cannot obtain this information itself), and write it to the first word of the heap object using `SET_HDR`. Then the pointer to the newly allocated hollow constructor is set as the return value.

**Combining both primops to obtain a new hollow constructor** It's time to show the two primops in action. Here is how we could allocate, for example, a hollow `Just` in a compact region:

<sup>26</sup>We refer the reader to [Yorgey et al., 2012] for more information about promoting term-level objects to type-level ones in Haskell.

### 3.5. Compact Regions: a playground to implement the DPS Haskell API

```

1 case primop of
2   [...]
3   ReifyInfoPtrOp → \_ → -- we don't care about the function argument (# #)
4     opIntoRegsTy $ \[res] resTy → emitAssign (CmmLocal res) $ case resTy of
5       -- when the phantom type parameter is a lifted data constructor, extracts it as a DataCon
6       TyConApp _infoPtrPlaceholderTyCon [_typeParamKind, TyConApp tyCon _]
7         | Just dataCon ← isPromotedDataCon_maybe tyCon →
8           CmmLit (CmmLabel (
9             mkConInfoTableLabel (dataConName dataCon) DefinitionSite))
10        -- when the phantom type parameter is a Symbol, we extracts the symbol value in 'sym'
11        TyConApp _infoPtrPlaceholderTyCon [_typeParamKind, LitTy (StrTyLit sym)] →
12          CmmLit (CmmLabel (
13            mkCmmInfoLabel rtsUnitId (fsLit "stg_" `appendFS` sym)))
14        _ → [...] -- error when no pattern matches

```

Listing 3.8: reifyInfoPtr# implementation in compiler/GHC/StgToCmm/Prim.hs

```

1 // compactAddHollow#
2 // :: Compact# → Addr# → State# RealWorld → (# State# RealWorld, a #)
3 stg_compactAddHollowzh(P_ compact, W_ info) {
4   W_ pp, ptrs, nptrs, size, tag, hp;
5   P_ to, p; p = NULL; // p isn't actually used by ALLOCATE macro
6   again: MAYBE_GC(again); STK_CHK_GEN();
7
8   pp = compact + SIZEOF_StgHeader + OFFSET_StgCompactNFData_result;
9   ptrs = TO_W_(%INFO_PTRS(%STD_INFO(info)));
10  nptrs = TO_W_(%INFO_NPTRS(%STD_INFO(info)));
11  size = BYTES_TO_WDS(SIZEOF_StgHeader) + ptrs + nptrs;
12
13  ALLOCATE(compact, size, p, to, tag);
14  P_[pp] = to;
15  SET_HDR(to, info, CCS_SYSTEM);
16  #if defined(DEBUG)
17    ccall verifyCompact(compact);
18  #endif
19  return (P_[pp]);
20 }

```

Listing 3.9: compactAddHollow# implementation in rts/Compact.cmm

```

1 | hollowJust :: Maybe a = compactAddHollow#
2 |   region
3 |   (unsafeCoerceAddr (reifyInfoPtr# (##) = InfoPtrPlaceholder# 'Just ))

```

It's important to note that the expression `reifyInfoPtr# (##)` will be replaced at compile-time by a static value representing the info table pointer of `Just`; while the call to `compactAddHollow#` behaves as a normal function call, and will only be executed when the program runs.

**Built-in type family to go from a lifted constructor to the associated symbol** The internal primop `reifyInfoPtr#` that we just introduced uses a constructor lifted at type level as an input. So the fill function, which uses `reifyInfoPtr#` and `compactAddHollow#` under the hood, should also use a constructor lifted at type level as a way of selecting the hollow constructor that will be added to a structure with holes.

However, fill relies on `GHC.Generics` to obtain various informations on the chosen constructor (see Section 3.5.4), and in the `Generic` representation of a type, constructors are identified by their name (as type-level strings), which are distinct type-level entities than the constructors lifted at type level like we used in `reifyInfoPtr#`.

Consequently, we need a way to translate a constructor lifted at type level into the type-level string representing the name of this constructor<sup>27</sup>. This is the role of the type family `LCtorToSymbol` that we also added to GHC. It just inspects its (type-level) parameter representing a constructor, fetches its associated `DataCon` structure, and returns a type-level string (kind `Symbol`) carrying the constructor name, as presented in Listing 3.10.

```

1 | matchFamLCtorToSymbol :: [Type] → Maybe (CoAxiomRule, [Type], Type)
2 | matchFamLCtorToSymbol [kind, ty]
3 |   | TyConApp tyCon _ ← ty, Just dataCon ← isPromotedDataCon_maybe tyCon =
4 |     let symbolLit = (mkStrLitTy . occNameFS . occName . getName $ dataCon)
5 |     in Just (axLCtorToSymbolDef, [kind, ty], symbolLit)
6 | matchFamLCtorToSymbol tys = Nothing
7
8 | axLCtorToSymbolDef =
9 |   mkBinAxiom "LCtorToSymbolDef" typeLCtorToSymbolTyCon Just
10 |   (λcase { TyConApp tyCon _ → isPromotedDataCon_maybe tyCon ; _ → Nothing })
11 |   (λ_ dataCon → Just (mkStrLitTy . occNameFS . occName . getName $ dataCon))

```

Listing 3.10: `LCtorToSymbol` implementation in `compiler/GHC/Builtin/Types/Literal.hs`

**Putting it all together, and further evolutions** All these elements combined provide the low-level backbone needed to implement our fill function. The implementations presented above were designed to minimize changes to GHC itself, based on the idea that the fewer modifications

<sup>27</sup>We perform the translation in this direction because a type-level string alone does not uniquely identify a constructor. For example, `reifyInfoPtr## @"Just"` is ambiguous and provides the compiler with insufficient information to resolve it to the correct `Just` constructor. In contrast, using the promoted constructor, as in `reifyInfoPtr## @'Just`, enables proper resolution.

required, the more realistic it would be for this feature to work well and be accepted into the main version of GHC, especially since destination-passing remains a relatively niche concern for such an industrial-grade compiler.

However, since this initial experimentation [Bagrel, 2023a], a pull request has been opened [Bagrel, 2024b] to gather community input on the topic, and we now appear to be moving toward a slightly more complete set of primitives than the three previously mentioned. In particular, primitive support for fill will likely be included in GHC itself (rather than existing solely in library code, as it does currently). At the time of writing, the interface design is still under discussion, and much of the implementation remains to be done (or be adapted from earlier experiments).

## 3.6 Evaluating the performance of DPS programming

It’s now time to see if our claims of performance are verified with our prototype destination-passing implementation [Bagrel, 2023b].

**Benchmarking methodology** We will compare programs in both naive style and DPS style, and see if we can observe differences in terms of speed but also memory efficiency. But first we must be careful in the way we measure time and space usage, especially since Haskell defaults to a lazy evaluation strategy.

In all DPS implementations we benchmark, the program output is stored in a compact region (as required). As noted in Section 3.5.1, compact regions enforce strictness; the structure is fully evaluated. While this may be suboptimal in some cases, it simplifies benchmarking by ensuring complete evaluation of the result.

For naive implementations, we must choose how to force full evaluation. One option is to keep the result in the GC heap and use `Control.DeepSeq.force` to recursively evaluate each thunk. Alternatively, we can copy the result to a compact region using `Data.Compact.compact`, which enforces strictness by default.

Copying into a compact region is only really desirable for a handful of programs, for which the result is held in memory for a long time and used in full (as the unused parts cannot be collected if it is in a compact region). Still, `compact` is sometimes faster than `force`. We therefore benchmark naive implementations primarily with `force`, but also with `compact` (noted with a `.copyCR` suffix) when this appears beneficial —either because storing the result in a compact region is desirable (e.g., in the parser example), or when it yields significantly better performance.

All charts have a relative scale on the Y axis (for both time and memory). The baseline is the time taken and the peak memory used by the method of reference, which is plotted in navy blue. Thus, the absolute scale differs for each input size, with 1.0 corresponding to the reference method’s value at that size. For memory charts, all series (*peak*, *allocated*, and *copied*) use the peak memory value of the method of reference as a baseline, so that values across all series at a given size are directly comparable.

**About memory reporting** Accurate memory reporting in Haskell is challenging. When benchmarks are run via `Tasty.Bench`, each is executed repeatedly until time results fall within a target deviation. `Tasty.Bench` also reports three memory metrics: allocated memory, copied

volume during garbage collection, and peak memory. Unfortunately, allocated memory does not include allocations in compact regions, making it unsuitable as a baseline. We therefore use peak memory as a baseline, which approximates how RAM hungry a given implementation is.

However, if we launch a full suite of benchmarks with **Tasty.Bench**, then the peak memory value reported can only ever increase across the whole run, and isn't reset when benchmarking a different implementation of the suite. We tried to solve this by running the benchmark of each implementation+size separately (instead of launching a full suite), so that each implementation can have a proper peak memory reporting. Yet even then, **Tasty.Bench** always report at least 69 MB of peak memory use, even if the given case uses far less (as we can deduce from the associated allocated and copied values).

Consequently, in addition to the **Tasty** benchmarks, we ran each implementation+size separately, 10 times, with RTS options `+I +s`, to get a more accurate reading of peak memory use. In this benchmarking mode, we observed a minimum of 6 MB of peak memory —accounting for the Haskell runtime and other boilerplate— which is quite better than the 69 MB reported by **Tasty.Bench**.

Still, many programs report exactly 6 MB of peak memory, while allocating between 0 and 3 MB (on average 0.5 MB). This shows that the reported peak memory does not accurately reflect the actual memory used by the implementation itself —it consistently overestimates usage by 3 to 6 MB, typically 5.5 MB. Based on this, we decided to subtract 5.5 MB from all peak memory readings equal to or above 10.5 MB to obtain an adjusted peak memory value. We do not show the data points that have a peak reading below 10.5 MB, as the margin of error, up to 2.5 MB, would represent more than half of the adjusted value.

When we don't have a trusted data point for the peak memory value of the reference method, we instead use an arbitrary origin for that input size (that is computed to preserve the shape of the copied and allocated curves). That way, we can still easily compare the other values with one another.

**Execution environment** We launch the benchmark of each implementation at a given size in isolation, either manually or through **Tasty.Bench**, with RTS options `+I +s`. We do not set any other runtime option; in particular, we do *not* use multithreading or configure any particular garbage collection option.

All programs are compiled with optimization `-O2`, with a version of GHC 9.12 modified to incorporate the changes initially presented in [Bagrel, 2023a] (which were initially designed for GHC 9.8).

Benchmarks have been conducted on a laptop under Kubuntu 22.04 with Intel i7-1165G7 @ 2.80 GHz CPU, 32 GB RAM, with power supply connected.

### 3.6.1 Concatenating lists and difference lists

We compared three implementations for list concatenation.

The first one, `concatListRight.force`, uses usual linked lists, and has calls to `(++)` nested to the right, giving the most optimal context for list concatenation: it should run in  $\mathcal{O}(n)$  time. We only include it as a point of reference, since it isn't the most common use-case for concatenation in practice. In real-world programs, list concatenation is often nested to the left, for example

### 3.6. Evaluating the performance of DPS programming

Figure 3.11: Benchmark of iterated concatenations on lists and difference lists

when appending lines to a log before eventually flushing it to disk. We chose not to include the version with calls to `(++)` nested to the left, as its time and memory consumption grow so rapidly that it renders the rest of the graph unreadable.

For the two other implementations, the calls to `concat` are nested to the left. The implementation `concatDListFunLeft.force` uses function-backed difference lists, and `concatDListDpsLeft` uses destination-backed ones (from Section 3.3.1). They should still run in  $\mathcal{O}(n)$  however, thanks to difference list magic.

We see in Figure 3.11 that the destination-backed difference lists have a slightly reduced memory consumption and lower runtime (about 10 %) compared to the two other implementations, for very large datasets only, in exchange of being quite slower and less memory efficient for all the smaller datasets. It’s a trend that we will see for the rest of the benchmarks: for very large datasets, garbage collection becomes very costly, and the destination-passing implementations shine not really by being faster to create or process data, but rather by avoiding garbage collection on large data trees that are still live. It’s much cheaper to collect garbage (e.g. the `Ampar` or `Dest` wrappers in the GC heap) than to preserve non-garbage.

Compared to the benchmarks initially presented in [Bagrel, 2024a], it seems that the performance of destination-based difference lists has improved, through more efficient handling of linear programs by the compiler, albeit the difference with naive implementations still isn’t substantial enough compared to what we could expect theoretically, especially when other simpler tweaks exist (notably, setting custom GC parameters at program’s launch).

#### 3.6.2 Breadth-first relabeling

For breadth-first tree traversal, we benchmark the destination-passing implementation of Section 3.3.2 against a fancy functional implementation based on *Phases* applicatives presented in [Gibbons et al., 2023]:

Figure 3.12: Benchmark of breadth-first tree relabeling

```

1  import Control.Monad.State.Lazy (runState, state)
2
3  data Phases m a where
4    Pure :: a → Phases m a
5    Link :: (a → b → c) → m a → Phases m b → Phases m c
6
7  instance Functor (Phases m) where ...
8  instance (Applicative m) ⇒ Applicative (Phases m) ...
9
10 now :: (Applicative m) ⇒ m a → Phases m a
11 now xs = Link (curry fst) xs (Pure ())
12
13 later :: (Applicative m) ⇒ Phases m a → Phases m a
14 later xs = Link (curry snd) (pure ()) xs
15
16 runPhases :: (Applicative m) ⇒ Phases m a → m a
17 runPhases (Pure x) = pure x
18 runPhases (Link f xs ys) = pure f <*> xs <*> runPhases ys
19
20 traverseBFS :: (Applicative m) ⇒ (a → m b) → BinTree a → Phases m (BinTree b)
21 traverseBFS _ Nil = pure Nil
22 traverseBFS f (Node x tl tr) =
23   pure Node <*> now (f x) <*> later ((traverseBFS f) tl) <*> later ((traverseBFS f) tr)
24
25 relabelPh :: BinTree () → (BinTree Int, Int)
26 relabelPh tree = runState (runPhases $ traverseBFS (\_ → state (\s → (s, s + 1))) tree) 0

```

### 3.6. Evaluating the performance of DPS programming

Figure 3.13: Benchmark of S-expression parser

We see in part Figure 3.12 that the destination-based tree traversal is about five times more efficient, both time-wise and memory-wise, than the implementation from Gibbons et al. [2023]. We must admit though that we didn't particularly try to optimize the performance of the *Phases* implementation as much as we did for our DPS framework in general.

This is a good example of a program for which the destination-passing version is almost as natural to write as the usual functional-style one, but performs significantly better even at smaller sizes.

#### 3.6.3 Parsing S-expressions

In Figure 3.13, we compare the naive and DPS implementations of the S-expression parser presented in Section 3.5.2. For this particular program, using compact regions is interesting even without destination-passing considerations, as it will reduce the GC load of the application as long as the data is held in memory (which is quite usual with parsed documents). Thus, we benchmark the naive version twice: once where the results stays in the GC heap and is evaluated with `force` (its name is suffixed with a star), and once to produce a result that we copy in a compact region (`copyCR`).

The DPS implementation starts by being less efficient than the naive versions for small inputs, but gets significantly better than the two other implementations tested as soon as garbage collection kicks in (we see it by the copied memory value rising very fast compared to the allocated and peak memory values, around  $2^{16}$ ).

On the dataset of size  $2^{19}$  to  $2^{25}$ , the DPS implementation uses 35-55% less time and 10-45% less memory at its peak than the two naive implementation, despite showing more allocations than `parseExpr.force`. All of this indicates that most of the data allocated in the GC heap by the DPS version is wrappers such as `Ampars` and `Dests` that just last one generation and thus can

Figure 3.14: Benchmark of map function on list

be discarded very early by the GC (as intended), without needing to be copied into the next generation, unlike the data nodes allocated by the naive versions that have to be persisted by the GC (by copying them).

It's slightly surprising to see that for this particular example, the `parseExpr.copyCR` version performs worse than `parseExpr.force` even for the largest datasets. In a real-world scenario though —where data is processed for some time after having been parsed instead of being discarded immediately— we expect the `copyCR` implementation to get an edge on garbage collection time (and thus, runtime) over the `force` version, but it would probably still be behind the DPS implementation which saves the copy of the result from the GC heap to the compact region.

### 3.6.4 Mapping a function over a list

In a strict functional language such as OCaml, the choice of implementation for the `map` function on lists is crucial as the naive, non tail-recursive one makes the stack grow linearly with the size of the processed list. To alleviate the issue, a strict tail-recursive implementation is possible (`mapTRS`), but it requires an extra  $\mathcal{O}(n)$  operation at the end of the processing to reverse the accumulator. In Haskell, the issue is of a lesser importance perhaps, as the lazy-by-default evaluation strategy makes the naive `map` (either `mapL` for full lazy behavior, or `mapSH` for strict head but lazy tail) run efficiently in constant space. Still, let see how our DPS versions compare.

With destinations, `map` can be implemented in a tail-recursive fashion too (`mapDpsTRS`), as explained in Section 2.2.2, without requiring the reverse operation that `mapTRS` needs, as the list is built directly in a top-down approach. Interestingly, thanks to destinations, `map` can alternatively be implemented as a left fold (`mapDpsFoldS`), as we also show below! In the following code excerpt, the `!` in front of a variable name denotes a strict binding, so the expression assigned to the variable will be evaluated to weak-head normal form before the body of the `let` is evaluated:

```
1 | append = UDest [t] → t → UDest [t]
```

```

2 | d `append` x = case d &fill @'(:) of (dh, dt) → dh &fillLeaf x ; dt
3 |
4 | mapDpsTRS _ [] d = d &fill @'[]
5 | mapDpsTRS f (x : xs) d = let !y = f x ; !d' = d `append` y in mapDpsTRS f xs d'
6 |
7 | mapDpsFoldS f l dl = fill @'[] (foldl' (\d x → let !y = f x in d `append` y) d l)

```

Figure 3.14 presents the results of the different implementations. First, we confirm that the most naive `mapL.force` is performing really well given its simplicity. We also see that the strict functional tail-recursive implementation `mapTRS` is not particularly interesting for a language like Haskell (even in its strict head, lazy tail variant that isn't shown in the chart, but got similar results), as it performs worse than all the other implementations both time and memory-wise.

For `mapSH`, the situation is a bit more complex. With the `force` evaluation method, it performs partially better, partially worse than the reference implementation `mapL.force` depending on the input size; but with copy to compact region in guise of deep evaluation, it achieves the smallest possible time for  $2^{16}$  and  $2^{22}$  sizes, surpassing the destination-based implementations by a few percents, with equally good peak memory use too. We can't really explain why we get so better results with copy to compact region for this particular implementation though; but it deserved to be included for being the top-performer for a few sizes.

Finally, the destination-based implementations `mapDpsTRS` and `mapDpsFoldS` present both very honorable performance, with 20-45% less time and up to 25% peak memory saving compared to the reference implementation for most datasets starting from  $2^{16}$  size. However, as we said before, the performance of DPS Haskell on small lists is still fairly disappointing. Reducing the overhead of destination-passing should probably be a focus of future refinements of the DPS Haskell implementation.

As a side note, Bour, Clément, and Scherer [2021] showed that in OCaml, the equivalent of `mapDpsTRS` is always more performant time-wise (15-50% less time) than the equivalent of `mapTRS`. However, their destination-passing system is used only at the compiler's intermediate language level, which perhaps allow for more aggressive optimizations than what we can achieve at the source level.

## 3.7 Conclusion

Programming with destinations definitely has a place in practical functional programming, as shown by the recent adoption of *Tail Modulo Cons* [Bour, Clément, and Scherer, 2021] in the OCaml compiler. In this chapter, we have shown how we can take most ideas from  $\lambda_d$  (Chapter 2) and adapt them to allow safe destination passing in Haskell, without modifying the core principles of this existing language. We also showed that most of the examples presented in chapter Chapter 2 can be implemented in DPS Haskell with little to no adaptations required, and we also emphasized how our particular implementation of destination passing for Haskell can help to improve the performance of programs in which garbage collection is very costly. To that extend, we rely on the *compact regions* [Yang et al., 2015] memory management scheme for Haskell; but our work also extend the way in which compact regions can be used efficiently.

Finally, we also demonstrated practical gains brought by destination-passing for some of the algorithms we presented all along this thesis; even though our DPS Haskell implementation is a bit heavyweight still and thus doesn't always let the destination-based algorithms match the theoretical performance expectations.

In this chapter, we could only use DPS Haskell for structures carrying unrestricted data. This was decided to keep a (relatively) simple API while avoiding the issues of scope escape (Section 2.3). In the next chapter, we'll revisit this limitation and find ways to modify DPS Haskell so that we can safely store linear resources in structures with holes.

## Chapter 4

# Extending DPS support in Haskell for linear data structures

*This chapter builds directly on the contents of the previous one and presupposes a detailed understanding of the concepts and results established therein.*

The main issue with the approach of our DPS Haskell API developed in ?? is that data structures built using destination filling cannot store linear data. This is the consequence of having a lot of flexibility in the way destinations can be used, without a system of ages to prevent scope escape in a fine-grained manner. So we had to use *unrestrictedness* as a barrier so that destinations cannot escape their scope.

Previous works however, such as [Minamide, 1998], or [Lorenzen, Leijen, Swierstra, and Lindley, 2024], would allow for efficient queues (see Section 2.2.3) or any structure with holes to store linear data, without issues with scope escape. Mainly because they don’t have a concept of destinations; in these works we can only fill holes in a structure by interacting with the incomplete structure itself (the *ampar*). So we ought to find a way for our Haskell implementation to be at least as expressive as these works.

### 4.1 Challenges of destinations for linear data —scope escape, updated

Starting from this point, we will say *linear destination* for an object of type `[1T]` or corresponding `Dest 1 t`, that is, a destination that can host linear data. Similarly, an *unrestricted destination* is an object of type `[ωT]` or `Dest ω t`. Regardless, a destination is always, itself, a resource that must be managed linearly. Finally, in the main part of this section, we omit compact region details, for clarity of exposition.

If we want to allow destinations to be filled with linear data, we have to be extremely careful about potential scope escape (see Section 2.3). One observation is that scope escape can only happen when we let the user fill an older linear destination in a newer scope. Because only linear destinations can be filled with another destination; and we’ve seen in Section 2.3 that filling a newer destination with an older one doesn’t cause scope escape; only filling an older one with a newer one does.

A potential remedy would be to not allow linear destinations to be filled using `fillLeaf` or `fillComp` functions. Instead, linear destinations could only be filled by operating on the ampar they come from, as in [Minamide, 1998; Lorenzen, Leijen, Swierstra, and Lindley, 2024]. That way, we’re sure we can only fill the freshest linear destinations (as destinations start to age when they are made accessible in a new scope with `updWith`; so destinations still on the right side of a closed ampar are the fresher than any other destination in the context). We will use the base name `extend` for this new family of operators that operate directly on an ampar to fill its destinations. Unrestricted destinations, on the other hand, can still be used with the various fill functions. We should note that filling a destination with a hollow constructor cannot cause any scope escape issues, so it’s safe to use `fill @'Ctor` on both linear and unrestricted destinations. Let’s see what this updated API would look like:

```

1 | data Ampar s t
2 | data Dest m t -- m is the multiplicity, either 1 or ω
3 | newAmpar :: Token → Ampar s (Dest 1 s)
4 | updWith :: Ampar s t → (t → u) → Ampar s u
5 |
6 | -- for unrestricted destinations
7 | fillLeaf :: t → Dest ω t → ()
8 |
9 | -- for linear destinations
10 | extendLeaf :: t → Ampar s (Dest 1 t) → Ampar s ()

```

The idea is that `extendLeaf` is a way of opening a new scope, filling the linear destination belonging to that fresh scope, and closing it immediately afterwards, without letting the user interfere. So we could think that in `extendLeaf (Ampar struct d) val`, the linear destination `d` which gets filled by `extendLeaf` would be always strictly younger than `val` which gets stored into it, preventing scope escape (recall the sane example of Section 2.3, where an older destination is stored into a younger one with no issues).

Except...it doesn’t work:

```

1 | newAmpar tok0 `updWith` \(d0 :: Dest 1 (Dest 1 t)) →
2 |   newAmpar tok1 `updWith` \(d1 :: Dest 1 t) →
3 |     (newAmpar tok2 `updWith` \(d2 :: Dest ω ()) → d2 &fillLeaf () ; d0) &extendLeaf d1

```

In this particularly convoluted example—which nonetheless typechecks given the API described above<sup>28</sup>— an old destination `d0` is hidden inside the nest of a fresher one `d2` that we’ve just consumed. So we have an ampar (`newAmpar `updWith` \(d2 → d2 &fillLeaf () ; d0)`) whose right-hand side contains a destination `d0` which isn’t its own, but comes from a previous scope. However, it is indistinguishable from an ampar whose right side contains only its own destinations, if we just look at the types. So we are allowed to use `extendLeaf` on the cursed ampar, which causes scope escape (as `d1` get stored in the outermost ampar)!

There seems to be an inevitable friction between having a capturing `updWith` function, and having safe linear destinations, when we don’t have a proper age system to ensure there is no cheating with scopes.

<sup>28</sup>It would, however, be rejected by  $\lambda_d$ , as `d0` would have age  $\uparrow^2$  when used as a variable in the innermost scope, which is disallowed by rule  $\lambda_d\text{-TY/ID}$ .

**Restricting `updWith`** If we want to prevent older destinations from hiding in newer ampars, we can ask for `updWith` to *not* capture any linear resource. That way, the only destinations accessible and usable in the scope of `updWith` are the one coming immediately from the ampar being opened.

This is done by changing the signature from `updWith :: Ampar s t  $\multimap$  (t  $\multimap$  u)  $\multimap$  Ampar s u` to `updWith :: Ampar s t  $\multimap$  (t  $\multimap$  u)  $\rightarrow$  Ampar s u`. Notice the unrestricted function arrow  $\rightarrow$ : it means the linear function supplied by the user must not capture anything linear (but still must use its argument linearly). Adding this drastic restriction has many consequences.

First, obviously, we cannot use any linear resource coming from outer scopes inside the scope of `updWith`. In particular, we cannot use a `Token` coming from the top-level linear scope (we described how convenient it is to just have one top-level linear scope in Section 1.8). Instead, we have to start a new nested linear scope (by calling `withToken`) if we want to create new ampars in the body of `updWith`, or tweak `updWith` to also provide a linear token to the inner scope, which gives `updWithToken :: Ampar s t  $\multimap$  ((t, Token)  $\multimap$  u)  $\rightarrow$  Ampar s u` (the ampar on which `updWithToken` operates is a linear resource on which we can base the chain of linearity that threads through the new token).

As a side note, even with the restriction on `updWith`, we still cannot fill linear destinations using a `fillLeaf` or `fillComp` function, for two main reasons. First, we cannot bring linear resources into scope in the first place, so we rarely have anything useful to fill into a linear destination. Second, allowing `fillLeaf` to operate on linear destinations could enable interactions between sibling destinations originating from the same scope, as described in Section 2.3. In earlier chapters, the restrictions put in place to prevent proper scope escape also happened to prevent such interaction between sibling destinations; but this is not the case here. Let’s see this with an example:

```

1 | fromAmpar' (
2 |   newAmpar @(t, Dest 1 t) tok `updWith` \ (d :: Dest 1 (t, Dest 1 t))  $\rightarrow$ 
3 |     case (d &fill @'(),) of (dt :: Dest 1 t, ddt :: Dest 1 (Dest 1 t))  $\rightarrow$ 
4 |       ddt &fillLeaf dt
5 | )

```

Here, we create a new ampar for a pair of a `t` and a `Dest 1 t`. After filling the root destination `d` with a hollow pair constructor, we get two destinations, `dt` and `ddt`. If we have access to a `fillLeaf` function operating with a linear destination on the left, we can actually put `dt` into `ddt`. Because we’ve consumed the two destinations and unit is returned, it seems that the ampar is complete, while in fact we’ve never provided a value of type `t` for the first field of the pair! So the structure is still incomplete while we are allowed to call `fromAmpar'` on it and read it!

This demonstrates that even with the restriction on `updWith` (which prevents capturing linear resources), allowing `fillLeaf` or `fillComp` to operate on linear destinations would still be unsafe.

## 4.2 Completing the extend family of functions for ampars with a single hole

We’ve just seen that to use linear destinations safely, we need operators that work on closed ampars directly, instead of destinations. In fact, that is exactly what happens in [Minamide, 1998], or [Lorenzen, Leijen, Swierstra, and Lindley, 2024]: they only allow incomplete structures with one hole, and extending the structure happens by manipulating the whole incomplete structure itself, not destinations (as they don’t exist in these works).

So as we just did with `extendLeaf` above, we’ll be designing new operators for ampars with only one hole, so exactly one destination on their right-hand side.

**The generic extend function** Similarly to the `fill @'Ctor` function (see ?? and Section 3.5.4), we would like an `extend @'Ctor` function that let us extend an ampar having only one hole with a new arbitrary hollow constructor. However, unlike `fill @'Ctor` that can return a variable number of destinations (e.g. `fill @'(:)` returns two new destinations), we must design a function `extend @'Ctor` that takes several values as an input to fill directly into all except one of the fields of the hollow constructor, so that only one new hole remains, and only one new destination is created<sup>29</sup>. The signature of such a function becomes a bit cumbersome to account for its genericity, as shown below:

```

1 | extend = ∀ lCtor k t m s fiTys kthFiTy othFiTys.
2 |     (OnlyLinear lCtor t,
3 |     FieldTypes lCtor t ~ fiTys,
4 |     At k fiTys ~ kthFiTy, Remove k fiTys ~ othFiTys) ⇒
5 |     othFiTys %m→ Ampar s (Dest m t) → Ampar s (Dest m kthFiTy)

```

There’s a lot to decipher here. `OnlyLinear lCtor t` is a constraint that asks for the chosen data constructor to only have linear fields (more about that in a moment). `FieldTypes` is a type family that returns the types of the fields for a given constructor (specified `lCtor` and the type `t` to which the constructor belongs). For example, `FieldTypes '(:) [Int]` resolves to `(Int, [Int])`. `At k` is a type family that returns the  $k^{\text{th}}$  element (i.e. type) of a tuple type, and similarly, `Remove k` returns the same tuple type it is given, with the  $k^{\text{th}}$  removed.

The symbol `~` is for type equality constraint, and can be used as above as a way to bind type variables to complex type-level expressions in a function or type class signature. Above, we say that `fiTys` represents all field types of `lCtor`, `kthFiTy` is the  $k^{\text{th}}$  of these, and `othFiTys` is all the remaining field types except the  $k^{\text{th}}$  one, in a tuple if there are more than one remaining type.

For instance, in `extend @'(:) @0 @[Int]`, `kthFiTy` is `Int`, and `othFiTys` is `[Int]` (not in tuple form because there is only one remaining type). Conversely, in `extend @'(:) @1 @[Int]`, `kthFiTy` is `[Int]`, and `othFiTys` is just `Int`.

<sup>29</sup>Alternatively, it’s still possible to use `updWith` to access a linear destination, then use `fill @'(:)` on it, creating two new linear destinations. But then we can’t use the `extendLeaf` function teased above to fill these destinations with complete values, because `extendLeaf` only works on an ampar with just a single destination on the right-hand side, and `fillLeaf` only works on unrestricted destinations.

#### 4.2. Completing the */extend/* family of functions for ampars with a single hole

In practice, such a signature means that `extend` takes an ampar whose right side is a destination of type `t`, with multiplicity `m`<sup>30</sup>. It then allocates a new hollow constructor (specified by `lctor`), consumes `othFiTys` at multiplicity `m` to fill all the fields of the new hollow constructor except the `kth` one, and then returns a destination with same multiplicity `m` for that remaining field of type `kthFiTy`.

For example, the `append :: DList t → t → DList t` function on difference lists can be expressed directly with `extend`. So far, `DList` could only store unrestricted elements, but now, we can use difference lists to carry linear elements!

```
1 | type DList t = Ampar [t] (Dest 1 [t])
2 |
3 | append :: DList t → t → DList t
4 | dlist `append` x = dlist &extend @'(:) @1 x
```

We can also use `extend` to define and use *zipper* trees (in the light of [Huet, 1997; Lorenzen, Leijen, Swierstra, and Lindley, 2024]) that can hold linear data:

```
1 | data Tree t = Nil | Node (Tree t) t (Tree t)
2 | type ZipperTree t = Ampar (Tree t) (Dest 1 (Tree t))
3 |
4 | nodeL :: ZipperTree t → t → Tree t → ZipperTree t
5 | nodeL parent x rtree = parent &extend @'Node @0 (x, rtree)
6 |
7 | nodeR :: ZipperTree t → Tree t → t → ZipperTree t
8 | nodeR parent ltree x = parent &extend @'Node @2 (ltree, x)
```

Note that `extend` doesn't support constructors with 0 fields (it would make the signature of the function way to complex). But 0-ary constructors can be written to the structure like any other complete value anyway, with `extendLeaf`:

```
1 | extendLeaf :: ∀ s t m. t %m→ Ampar s (Dest m t) → Ampar s ()
```

Here we've also made `extendLeaf` multiplicity-polymorphic, compared to the initial version presented in Section 4.1, but its behavior stays the same.

It is a bit pointless in fact to return an `Ampar s ()` to the user from a call to `extendLeaf`; it's better to directly extract the completed structure of type `s`:

```
1 | fromAmparWithLeaf :: ∀ s t m. t %m→ Ampar s (Dest m t) → s
2 | fromAmparWithLeaf = fromAmpar' . extendLeaf
3 |
4 | -- we use it to implement the remaining operator for zipper trees
5 | done :: ZipperTree t → Tree t
6 | done parent = parent &fromAmparWithLeaf Nil
```

<sup>30</sup>That way, we can use `extend` on an ampar with either a linear or unrestricted destination on the right, even though unrestricted destinations can be manipulated directly in a more flexible fashion by using the functions from the fill family.

**Multiplicity of fields of a constructor and `extendUr`** Above, in the definition of `extend`, we considered that the constructor represented by `lCtor` had only linear fields, as indicated by the constraint `OnlyLinear lCtor t`. Indeed, the multiplicity `m` at which we consume the values for the other fields, and at which we return the new destination, are the same as the multiplicity of the parent destination.

In  $\lambda_d$ , every data constructor has linear fields, except the exponential constructor `Modm` which has a single field of mode `m`. In Haskell however, constructors have only linear fields by default, but can have unrestricted fields when the corresponding datatype is defined with GADT syntax and that an unrestricted arrow  $\rightarrow$  is following the field's type. An unrestricted field is a way to hold unrestricted data without needing an explicit `Ur` layer.

Ideally, we should thus refine the `extend` function further, and be polymorphic over the multiplicity of each field. However, to this date, we cannot get the information about field multiplicities through `GHC.Generics`, that we use in our practical implementation. So, for now, it doesn't seem easy to modify the `extend` function even more to account for arbitrary multiplicity on fields. But there is also another consequence: it means we have to add a dedicated version of `extend` for the `Ur` constructor:

```
1 | extendUr :: ∀ s t m. Ampar s (Dest m (Ur t)) → Ampar s (Dest w t)
```

Given that `m · w = w` for any `m`, the `extendUr` function can operate on an ampar with either a linear or unrestricted destination, but always returns an ampar with an unrestricted destination.

Using `extendUr` is the primary way, in this world, to obtain an initial unrestricted destination `Dest w t`, as `newAmpar` initially spawns an ampar with just a linear destination on the right.

**Composition of incomplete structures with `extendComp`** The last function we need in this setting is `extendComp`, which plugs two ampars together:

```
1 | extendComp :: ∀ s t u. Ampar t u → Ampar s (Dest 1 t) → Ampar s u
```

In `extendComp`, the destination in the parent ampar must be linear, as we already mentioned in Section 2.5.2. Otherwise, the following exploit becomes possible:

```
1 | extendCompFaulty :: ∀ s t u m. Ampar t u → Ampar s (Dest m t) → Ampar s u
2 |
3 | parentAmpar :: Ampar (Ur t) (Dest w t) = newAmpar tok1 & extendUr
4 | -- resolves to Ampar (Ur [h]) (Dest →h)
5 |
6 | childAmpar :: Ampar Int (Dest 1 Int) = newAmpar tok2
7 | -- resolves to Ampar ([h']) (Dest →h')
8 |
9 | resAmpar :: Ampar (Ur t) (Dest 1 t) = parentAmpar & extendCompFaulty freshAmpar
10 | -- resolves to Ampar (Ur [h']) (Dest →h')
11 |
12 | let Ur (linearRes') = resAmpar & fromAmparWithLeaf linearResourceDoNotDuplicate in
13 | (linearRes', linearRes')
```

### 4.3. Arbitrary type on the right-hand side of ampars storing linear data

With the code above, we create an ampar `resAmpar` with a linear destination pointing to an unrestricted hole. This happens because the ampar resulting from a composition inherits whatever was on the right of the child ampar (here a linear destination `Dest → h' :: Dest 1 Int`). But the left side of the child ampar has been grafted into the unrestricted hole `h` of the parent ampar. As a result, `h` becomes transitively unrestricted, while its corresponding destination remains linear. This enables the duplication of linear resources, as shown in the last line, so we must prevent it. For the same reason, we cannot define a function `fillComp :: Ampar t u → Dest ω t → u` in this setting.<sup>31</sup> In Chapter 3, this issue did not arise because all destinations were unrestricted by design.

What we can do, however, is define alternative versions of `extendComp` and `fillComp` that operate on unrestricted destinations, with a slightly modified signature, that makes them safe this time:

```
1 | extendUComp :: ∀ s t u. Ampar (Ur t) u → Ampar s (Dest ω t) → Ampar s u
2 | fillUComp  :: ∀ t u. Ampar (Ur t) u → Dest ω t → u
```

Here, the child ampar is required to be an unrestricted structure (as indicated by the leading `Ur`). This ensures that any destination appearing in `u` is already unrestricted. As a result, we eliminate the linearity exploit and recover the same composition behavior we had in Chapter 3 for `UAmpars`.

## 4.3 Arbitrary type on the right-hand side of ampars storing linear data

Being limited to only one destination on the right-hand side of ampars is not ideal. Indeed, we stay at the same expressivity level as existing work, and we lose part of the flexibility that made  $\lambda_d$  innovative in the first place.

Supporting multiple linear destinations on the right-hand side of ampars introduces significant complexity however. In the previous section, with only one destination per ampar, we avoided scope escape by requiring the user to interact with the ampar directly, rather than with the destination itself. This was straightforward, as there was no ambiguity —the single destination was the only possible target of the `extend` operation. By contrast, if we now allow arbitrary types on the right-hand side, but still aim to restrict direct user access to destinations (for the same reasons as above; `updWith` is now non-capturing, and we want to prevent scope escape and malicious interaction between sibling destinations), we must introduce a mechanism for users to indicate which specific destination they intend to operate on.

One idea for that is to ask the user for a linear lens. First, let's define what a lens is.

Lenses are pairs of getters and setters that enable convenient handling of immutable data structures in functional programming languages. A lens of type `Lens t1 t2 u1 u2` has two components (at least conceptually):

- a getter function to access a value of type `u1` somewhere inside a structure of type `t1`, which establishes the *focus* of the lens;

---

<sup>31</sup>Recall that we already ruled out defining fill-like functions for linear destinations since the first section of this chapter.

- a function to transform a structure of type **t1** into a structure of type **t2** by replacing the focused value of type **u1** by a value of type **u2**. In particular, when **u1=u2**, then **t1=t2**, and thus this function acts as an (immutable) setter for the focused value.

In their simplest expressions, non-linear lenses are represented by the following datatype:

```

1 | data LensNL t1 t2 u1 u2 = LensNL
2 |   { view :: t1 → u1 -- just get u1 out of t1, discard the rest
3 |     , update :: t1 → u2 → t2 -- discard the u1 inside t1 and replace it with a u2 to make a t2
4 |   }

```

Given a data structure **Triple** with 3 fields, let's create a lens to focus on the first field:

```

1 | data Triple s t u = Triple { first :: s, second :: t, third :: u }
2 |
3 | fstNL :: LensNL (Triple s t u) (Triple s' t u) s s'
4 | fstNL = LensNL { view = \(Triple x y z) → x
5 |                  , update = \(Triple x y z) → x' → Triple x' y z }

```

With a non-linear lens **LensNL** such as above, if we use the **view** component, then we consume a value of type **t1** but discard most of it except the part of type **u1**. If we use the **update** component, it's the opposite; we discard the part of type **u1** but keep all the rest of the original **t1**.

For linear lenses, that we'll introduce now, we are not allowed to use the **view** and **update** components separately; otherwise we could drop parts of the original structure of type **t1**, as we've just seen. So instead, we group the two functions **view** and **update** into a single one:

```

1 | newtype Lens t1 t2 u1 u2 = Lens (t1 → (u1, u2 → t2))

```

With a linear lens of type **Lens t1 t2 u1 u2**, we can split a structure of type **t1** into a pair of a value of type **u1** (the focus), and a closure of type **u2 → t2** that carries all the rest of the original **t1**, and is ready to produce a structure of type **t2** if we give it a **u2**. In other terms, this second component of type **u2 → t2** is really just a functional representation of a **t2** missing a **u2** to be complete. Both of the components of the pair have to be consumed if we want to respect linearity.

It's fairly immediate to update our **Triple** exemple for linear lenses:

```

1 | fst :: Lens (Triple s t u) (Triple s' t u) s s'
2 | fst = Lens (\(Triple x y z) → (x, \x' → Triple x' y z))
3 | --           captures x ↗           ↖ captures y and z

```

**Lenses to select destinations to operate on** With linear lenses that we just introduced, the user can specify which destination to operate on when using the new family of **extendFocused** functions. We also get, at the same time, a way to reinsert the newly produced destinations (for fields of the new hollow constructor), or the byproduct of the filling operation, at the exact position that was previously occupied by the destination we just consumed, on the right-hand side of the ampar (thanks to the dual nature of lenses, acting both as a form of getter and setter):

#### 4.3. Arbitrary type on the right-hand side of ampars storing linear data

```

1 | extendFocused :: ∀ lCtor u t1 t2 s m.
2 |   (OnlyLinear lCtor u) ⇒
3 |   Lens t1 t2 (Dest m u) (DestsOf lCtor m u) → Ampar s t1 → Ampar s t2
4 |
5 | extendWithNodeOnFst :: Ampar s (Triple (Dest m (Tree t1)) t2 t3)
6 |   → Ampar s (Triple (Dest m (Tree t1), Dest m t1, Dest m (Tree t1)) t2 t3)
7 | extendWithNodeOnFst ampar = ampar & fst extendFocused fst @'Node

```

Here, `extendFocused` takes a lens of type `Lens t1 t2 (Dest m u) (DestsOf lCtor m u)`, i.e., a lens that focuses on a `Dest m u` inside the right-hand side of type `t1` of the ampar, and let us build a new right-hand side of type `t2` for the resulting ampar, where the destination of type `Dest m u` is replaced by a value of type `DestsOf lCtor m u` (that is, a tuple with the new potential destinations).

The lens is taken as a non-linear argument by `extendFocused` (as indicated by the non-linear arrow  $\rightarrow$ ), so that it cannot capture any linear resource. So the lens is forced to be just a purely structural operation that can be applied as many times as we want on various values of type `t1`.

Nonetheless, we could have implemented `extendWithNodeOnFst` in terms of `updWith` and `fill @'Node`<sup>32</sup>. In fact, the added value of linear lenses becomes clear when designing the `extendFocusedLeaf` function, which for the first time (in the Haskell implementation), enables us to fill a linear destination with a value when the said destination is located within an arbitrary structure on the right-hand side of an ampar:

```

1 | extendFocusedLeaf :: ∀ u t1 t2 s m. u %m→ Lens t1 t2 (Dest m u) () → Ampar s t1 → Ampar s t2
2 |
3 | extendWithValOnFst :: t1 → Ampar s (Triple (Dest 1 t1) t2 t3) → Ampar s (Triple () t2 t3)
4 | extendWithValOnFst x ampar = ampar & extendFocusedLeaf fst x

```

No scope escape can happen here. As `updWith` is non-capturing, we're sure that the destinations on the right-hand side of an ampar are the ones pointing to the holes on its left-hand side (eliminating the issue presented at the end of Section 4.1). So like `extendLeaf`, the `extendFocusedLeaf` function can only be used to fill a newer destination with existing (thus, older) values. Likewise, we cannot have sibling destinations interacting with one another. Which means, we've reached our goal for this chapter!

For completeness, we finally define `extendFocusedUr`, `extendFocusedComp` and `extendFocusedUComp`, following the same pattern as for `extendFocusedLeaf`:

```

1 | extendFocusedUr :: ∀ u t1 t2 s m.
2 |   Lens t1 t2 (Dest m (Ur u)) (Dest w u) → Ampar s t1 → Ampar s t2
3 | extendFocusedComp :: ∀ u t1 t2 s u1 u2.
4 |   Ampar u1 u2 → Lens t1 t2 (Dest 1 u1) u2 → Ampar s t1 → Ampar s t2
5 | extendFocusedUComp :: ∀ u t1 t2 s u1 u2.
6 |   Ampar (Ur u1) u2 → Lens t1 t2 (Dest w u1) u2 → Ampar s t1 → Ampar s t2

```

Both of these functions are very similar to their respective one-hole versions `extendUr` and `extendComp`. In `extendFocusedUr`, we consume a destination of type `Dest m (Ur u)` and replace it with a destination of type `Dest w u`. In `extendFocusedComp`, we consume a destination of type `Dest 1 u1`, to which we write the left-hand side (of type `u1`) of the child ampar, and we replace

<sup>32</sup>As said previously, `fill @'Ctor` cannot cause scope escape and thus is safe to use for both linear and unrestricted destinations

this consumed destination with whatever was on the right-hand side (of type `u2`) of the child `ampar`. The only difference, between the `extend` and the corresponding `extendFocused` functions, is that the filling operation in the latter happens at a focused location on the right-hand side of an `ampar` instead of being made on the single destination at top level as in the former.

## 4.4 Breadth-first tree traversal, updated, and final API

The family of `extendFocused` functions, based on linear lenses, addresses the core challenge of safely filling destinations with linear data. Although the resulting interface is not entirely satisfactory —particularly from an ergonomic standpoint— it still strikes a reasonable compromise between expressiveness and complexity of the interface (given the constraint of working with the existing Haskell type system).

For instance, the DPS system supports two usable levels of nesting for destinations, allowing us to construct and use linear destinations of destinations (type `Dest 1 (Dest m t)`). This is in fact perfectly sufficient to implement non-trivial examples, such as the breadth-first traversal of a tree, but this time using the efficient, destination-based queues in Haskell! Let’s revisit these examples one last time. For the final part of this chapter, we also take compact region considerations into account (this mostly consists in adding `r` and `Region r` all over the function’s signatures). The code of efficient queues (and difference lists for linear data, that they are made of) is presented in Listing 4.1, and the code for updated breadth-first tree traversal is given in Listing 4.2.

These implementations derive directly from the various iterations and improvements we’ve made over the different lists, efficient queues and breadth-first traversal examples all along this document.

Notably though, we leverage both the `fill` and the `extend` families of functions in these examples. For instance, we reuse the implementation of difference lists presented in Section 4.2, for which we don’t need the flexibility brought by `updWith`, and instead rely on the `extend` functions so that we can store linear data in the difference lists (very similarly to what is presented in [Minamide, 1998; Lorenzen, Leijen, Swierstra, and Lindley, 2024]). On the other hand, the breadth-first tree traversal is still implemented using `updWith` and `fill`-like functions, which are essential for operating on the destinations stored in the queue.<sup>33</sup>

**Full, final API for DPS Haskell with linear destination support** In Listing 4.3, we sum up all the functions we’ve encountered in this chapter, that are needed to create an Haskell API as flexible as possible, while still being safe, to perform destination passing.

At the time of writing the thesis, we have not implemented this whole API yet, but we envision that there shouldn’t be any particular technical issue to do so. Indeed, the behavior of the `extend` operators derives directly from the corresponding `fill` functions, that already have a concrete implementation in [Bagrel, 2023b].

---

<sup>33</sup>It would not be possible to implement the breadth-first traversal using only `extend` functions with lens support. If it is possible at all, it would require more powerful *optics* (the broader family of abstractions that includes lenses), and the resulting code would likely be much more verbose.

```

1  type DList r t = Ampar r [t] (Dest r 1 [t])
2
3  newDList :: Region r ⇒ Token → DList r t
4  newDList = newAmpar @[t]
5
6  dListToList :: Region r ⇒ DList r t → [t]
7  dListToList dlist = fromAmpar' (dlist &extendLeaf [])
8
9  append :: Region r ⇒ DList r t → t → DList r t
10 append dlist x = dlist &extend @'(:) @1 x
11
12 -----
13
14 data EffQueue r t = EffQueue [t] (DList r t)
15
16 newEffQueue :: Region r ⇒ Token → EffQueue r t
17 newEffQueue tok = EffQueue [] (newDList tok)
18
19 singleton :: Region r ⇒ Token → t → EffQueue r t
20 singleton tok x = EffQueue [x] (newDList tok)
21
22 queueToList :: Region r ⇒ EffQueue r t → [t]
23 queueToList (EffQueue front back) = front ++ dListToList back
24
25 enqueue :: Region r ⇒ EffQueue r t → t → EffQueue r t
26 enqueue (EffQueue front back) x = EffQueue front (back `append` x)
27
28 dequeue :: Region r ⇒ EffQueue r t → Maybe (t, EffQueue r t)
29 dequeue (EffQueue front back) = case front of
30   [] → case tokenBesides back of (back, tok) → case (toList back) of
31     [] → drop tok ; Nothing
32     (x : xs) → Just (x, (EffQueue xs (newDList tok)))
33   (x : xs) → Just (x, (EffQueue xs back))

```

Listing 4.1: Efficient queue for linear data

## 4.5 Conclusion

In this chapter we took time to explore what happens when we relax the drastic restriction we had imposed in Chapter 3, namely, that destinations could only be filled with non-linear data (which, consequently, meant that ampars could only be used to store non-linear data).

In several careful steps, avoiding scope escape and similar dangers at every corner, we refined our DPS Haskell API to lift this limitation. First, by allowing the user to build ampars to store linear data, but only if they have only one hole each, in the light of the foundational works [Minamide, 1998; Lorenzen, Leijen, Swierstra, and Lindley, 2024]. This gave birth to the family of `extend` functions, that operate on ampars directly instead of destinations.

In a second step, we released yet another set of functions, denoted by `extendFocused`, that let the user fill ampars of arbitrary shapes, with no limit on the number of holes or destinations, with linear data. These functions also operate directly on an ampar, and let the user select the destination they want to focus on, inside the ampar, with a *linear lens* —that is, a convenient object that acts as both a getter and setter for immutable functional data structures.

In the end, we recover a system that is as close to  $\lambda_d$  (Chapter 2) as we could safely design within the existing type system of Haskell, with expressivity improvements over the initial DPS Haskell API. Of course, the ergonomics for filling linear destinations are not as smooth as in  $\lambda_d$ , but our newly gained flexibility let us implement a revised version of breadth-first tree traversal, that this time, used exactly the same algorithm and underlying data structures as the initial version proposed in Section 2.4.

The final API we obtain, after all these refinements, has not been implemented yet in Haskell, though we don't think that it will be particularly challenging, as most of the hard work for low-level operations has already been done in Section 3.5.

Finally, should time be available to devote to this topic in the future, it would be worth exploring how we can leverage the theoretical framework developed in Chapter 2 to formally prove that our proposed Haskell API in Section 4.4 is indeed safe.

```

1 data Tree t = Nil | Node t (Tree t) (Tree t)
2
3 relabelDps :: Region r => Token -> Tree t -> Tree Int
4 relabelDps tree = fst (mapAccumBfs (\st _ -> (st + 1, st)) 1 tree)
5
6 mapAccumBfs :: ∀ r s t u. Region r => Token -> (s -> t -> (s, u)) -> s -> Tree t -> (Tree u, s)
7 mapAccumBfs tok f s0 tree =
8   case fromAmpar (newAmpar @(Ur (Tree u)) tok `updWith` \du -> go s0 (singleton (Ur tree, du &fillUr)))
9   of (Ur outTree, Ur st) -> (outTree, st)
10  where
11    go :: s -> EffQueue r (Ur (Tree t), Dest r w (Tree u)) -> Ur s
12    go st q = case dequeue q of
13      Nothing -> Ur st
14      Just ((utree, dtree), q') -> case utree of
15        Ur Nil -> dtree &fill @'Nil ; go st q'

Listing 4.3: Destination-passing API for Haskell with support for linear destinations

# Related Work

This chapter situates *functional destination passing* within the broader landscape of related approaches to safe and controlled memory updates in functional programming. A particularly close and relevant theme is that of *functional data structures with holes*, since *destination passing* provides a flexible and principled way to manipulate such structures. However, despite their conceptual overlap, *functional destination passing* and *functional data structures with holes* remain slightly distinct in their nature.

*Functional destination passing* encompasses techniques where updates to write-once memory cells are exposed through a safe or at least controlled interface. In fact, in previous work, this interface has not often been directly exposed to programmers; instead, in these cases, *destination passing* is employed internally by compilers to optimize functional programs. This includes performance improvements for functional linked data structures (Section 1) and functional arrays (Section 2), which are written in the usual purely functional style but benefit from behind-the-scenes mutations to reduce allocations and improve performance, with no explicit user control. Ultimately, destinations can also be used in the operational semantics of a theoretical lambda-calculus (Section 3).

In contrast, *functional structures with holes* focus on allowing incomplete data structures, a.k.a. structures with holes, to exist as first-class values—that the user can manipulate explicitly—in a purely functional setting, and be completed or refined later. Completing these structures necessarily involves some form of memory update, but many systems (Sections 4 and 5) do not include an explicit notion of first-class write pointer (*destination*) to do the mutation. In contrast, this thesis explores how both *functional structures with holes* and *functional destination passing* can be combined effectively, leveraging the strengths of each to achieve more expressive manipulation patterns of functional data, always in a safe manner.

Both of these notions inherently involve mutation and uninitialized data and therefore require robust static guarantees to ensure safety. *Linear* and *uniqueness type systems* are thus commonly employed to enforce strict control over destinations or structures with holes, preventing unsafe updates and premature reads on incomplete structures. However, as demonstrated in this work, *linearity* alone is insufficient to capture the full range of safety and expressiveness we needed. Modal type systems (Section 6) are in that case particularly helpful to let us design a coherent and ergonomic type system, easily, for our specific needs. Complementary approaches such as *permission-based type systems* (Section 7) and resource lifetime management techniques *à la* Rust (Section 8) also play an important role to enforce fine-grained control over resources, which may be leveraged to control our destinations or structures with holes.

## 1 Tail modulo constructor

[Bour, Clément, and Scherer, 2021] focuses on the perennial problem that the map function on linked lists isn’t tail-recursive, hence consumes stack space. The map function can be made tail recursive, but at the cost of an extra reverse operation on the list. Their observation is that there’s a systematic transformation of functions where the only recursive call is under a data constructor application (e.g. *cons* in the map instance) to a destination-passing tail-recursive implementation.

Here again, there’s no destination in user land, only in the intermediate representation. However, there is a programmatic interface: the programmer annotates a function like

```
let[@tail_mod_cons] rec map =
```

to ask the compiler to perform the translation. The compiler will then throw an error if it can’t, making the optimization behavior entirely predictable. This has been included in the OCaml compiler since version 4.14, and is the one example we know of destinations built in a production-grade functional compiler.

Both our  $\lambda_d$  and DPS Haskell API allow to write the result of a tail-modulo-constructor transformation (that is, the destination-passing tail-recursive program) as a well-typed program in userland, which isn’t possible in OCaml. However, we don’t provide a way to do a similar automatic transformation itself.

On the flip-side, tail modulo constructor is too weak to handle our difference lists or breadth-first traversal examples. For the former, it misses first-class support for structure with holes; they can only exist in the background for the duration of a function being transformed. For breadth-first tree traversal, there is no obvious implementation in functional style with only one recursive call, so the tail modulo constructor transformation cannot be applied.

## 2 Destination-passing style for efficient memory management

Shaikhha et al. [2017] present a destination-based intermediate language for a functional array programming language, with destination-specific optimizations, that boasts near-C performance.

This another significant evidence to date of the benefits of destination-passing style for performance in functional languages, although their work is on array programming, while this PhD thesis focuses on linked data structures. They can therefore benefit from optimizations that are perhaps less valuable for us, such as allocating one contiguous memory chunk for several arrays.

The other difference between their work and ours is that their language is solely an intermediate language: it would be unsound to program in it manually. We, on the other hand, are proposing a type system to make it sound for the programmer to program directly with destinations.

We see these two aspects as complementing each other: good compiler optimizations are important to alleviate the burden from the programmer and allow high-level abstraction; having the possibility to use destinations in code affords the programmer more control, should they need it.

### 3 Semi-axiomatic sequent calculus

In [DeYoung, Pfenning, and Pruiksmas, 2020] constructors return to a destination rather than allocating memory. It is very unlike the other systems described in this section in that it's completely founded in the Curry-Howard isomorphism. Specifically it gives an interpretation of a sequent calculus which mixes Gentzen-style deduction rules and Hilbert-style axioms. As a consequence, the *par* connective is completely symmetric, and, unlike our  $\llbracket \mathbf{T} \rrbracket$  type, their dualization connective is involutive.

The cost of this elegance is that computations may try to pattern-match on a hole, in which case they must wait for the hole to be filled. So the semantics of holes is that of a future or a promise. In turns this requires the semantics of their calculus to be fully concurrent, which is a very different point in the design space.

### 4 A functional representation of data structures with a hole

The idea of using linear types as a foundation of a functional calculus in which incomplete data structures can exist and be composed as first class values dates back to [Minamide, 1998]. Our system is strongly inspired by theirs. In [Minamide, 1998], a first-class structure with a hole is called a *hole abstraction*. Hole abstractions are represented by a special kind of linear functions with bespoke restrictions. As with any function, we can't pattern-match on their output (or pass it to another function) until they have been applied; but they also have the restriction that we cannot pattern-match on their argument —the *hole variable*— as that one can only be used directly as argument of data constructors, or of other hole abstractions. The type of hole abstractions,  $(\mathbf{T}, \mathbf{S})\mathbf{hfun}$  is thus a weak form of linear function type  $\mathbf{T} \multimap \mathbf{S}$ .

In [Minamide, 1998], it's only ever possible to represent structures with a single hole. But this is a rather superficial restriction. The author doesn't comment on this, but we believe that this restriction only exists for convenience of the exposition: the language is lowered to a language without function abstraction and where composition is performed by combinators. While it's easy to write a combinator for single-argument-function composition, it's cumbersome to write combinators for functions with multiple arguments. But having multiple-hole data structures wouldn't have changed their system in any profound way.

The more important difference is that while their system is based on a type of linear functions, ours is based on the linear logic's "par" type. In classical linear logic, linear implication  $\mathbf{T} \multimap \mathbf{S}$  is reinterpreted as  $\mathbf{S} \wp \mathbf{T}^\perp$ . We, likewise, reinterpret  $(\mathbf{T}, \mathbf{S})\mathbf{hfun}$  as  $\mathbf{S} \ltimes \llbracket \mathbf{T} \rrbracket$  (a sort of weak "par").

A key consequence is that destinations —as first-class representations of holes— appear naturally in  $\lambda_d$ , while [Minamide, 1998] doesn't have them. This means that using [Minamide, 1998], one can implement the examples with difference lists and queues from Section 2.2.3, but couldn't do our breadth-first traversal example from Section 2.4, since it requires to be able to store destinations in a structure.

Nevertheless, we still retain the main restrictions that Minamide [1998] places on hole abstractions. For instance, we can't pattern-match on  $\mathbf{S}$  in (unapplied)  $(\mathbf{T}, \mathbf{S})\mathbf{hfun}$ ; so in  $\lambda_d$ , we can't act directly on the left-hand side  $\mathbf{S}$  of  $\mathbf{S} \ltimes \mathbf{T}$ , only on the right-hand side  $\mathbf{T}$ . Similarly, hole variables can only be used as arguments of constructors or hole abstractions; it's reflected in  $\lambda_d$  by the fact that the only way to act on destinations is via fill operations, with either hollow constructors or another *ampar*.

The ability to manipulate destinations, and in particular, store them, does come at a cost though: the system needs this additional notion of ages to ensure that destinations are used soundly. On the other hand, our system is strictly more general, in Minamide [1998]’s system can be embedded in  $\lambda_d$ , and if one stays in this fragment, we’re never confronted with ages.

## 5 Tail Recursion Modulo Context and The Functional Essence of Imperative Binary Search Trees

TODO

[Lorenzen, Leijen, Swierstra, and Lindley, 2024; Leijen and Lorenzen, 2025]

## 6 Oxidizing OCaml

Lorenzen, White, et al. [2024] present an extension of the OCaml type system to support modes. Their modes are split along three different “axes”, among which affinity and locality are comparable to our multiplicities and ages. Like our multiplicities, there are two modes for affinity *once* and *many*, though in [Lorenzen, White, et al., 2024], *once* supports weakening, whereas  $\lambda_d$ ’s *1* multiplicity is properly linear (proper linearity matters for destination lest we end up reading uninitialized memory).

Locality tracks scope. There are two locality modes, *local* (doesn’t escape the current scope) and *global* (can escape the current scope). The authors present their locality mode as a drastic simplification of Rust’s lifetime system, which nevertheless fits their need.

However, such a simplified system would be a bit too weak to track the scope of destinations. The observation is that if destinations from two nested scopes are given the same mode, then we can’t safely do anything with them, as it would be enough to reproduce the counterexamples of Section 2.3. So in order to type the breadth-first traversal example of Section 2.4, where destinations are stored in a structure, we need at least  $\nu$  (for the current scope),  $\uparrow$  (for the previous scope exactly), plus at least one extra mode for the rest of the scopes (destinations of this generic age cannot be safely used). It turns out that such systems with finitely many ages are incredibly easy to get wrong, and it was in fact much simpler to design a system with infinitely many ages.

## 7 Programming with Permissions in Mezzo

Protzenko and Pottier [2013] introduced the Mezzo programming language, in which mutable data structures can be freed into immutable ones after having been completed. This principle is used to some extent in their list standard library module, to mimic a form of DPS programming. An earlier appearance of DPS programming as a mean to achieve better performance in a mutable language can also be seen in [Larus, 1989].

## 8 Rust lifetimes

Rust uses a system of lifetimes (see e.g. [Pearce, 2021]) to ensure that borrows don't live longer than what they reference. It plays a similar role as our system of ages.

Rust lifetimes are symbolic. Borrows and moves generate constraints (inequalities of the form  $\alpha \leq \beta$ ) on the symbolic lifetimes. For instance, that a the lifetime of a reference is larger than the lifetime of any structure the reference is stored in. Without such constraints, Rust would have similar problems to those of Section 2.3. The borrow checker then checks that the constraints are solvable. This contrasts with  $\lambda_d$  where ages are set explicitly, with no analysis needed.

Another difference between the two systems is that  $\lambda_d$ 's ages (and modes in general) are relative. An explicit modality  $!_{\uparrow k}$  must be used when a part has an age different than its parent, and means that the part is  $k$  scope older than the parent. On the other hand, Rust's lifetimes are absolute, the lifetime of a part is tracked independently of the lifetime of its parent.

# Conclusion and future work

Destination passing is not a novel concept in programming language design. It was used early on —when manual memory management was essential even for simple programs— as a means to avoid unnecessary memory allocations for intermediate results.

It was then partially abandoned during the rise of object-oriented programming, which brought widespread adoption of automatic memory management. Today, however, we reexamine destination passing in the context of functional programming languages, with slightly different expectations.

For instance, we do not advocate a return to full manual memory management, as it was the case when destination passing was used in the past. Indeed, the ability to ignore memory concerns is, in most cases, a key benefit of modern languages. Rather, functional destination passing can pursue two goals: to allow compilers to optimize code by transforming it into destination-passing style automatically at compile time [Bour, Clément, and Scherer, 2021; Leijen and Lorenzen, 2025]; or, as demonstrated in this thesis, to provide programmers with the ability to manually opt in to destination passing for specific sections of functional code where improved performance or expressivity is needed.

Because destination passing is inherently imperative, it must be carefully adapted for use in functional programming languages, particularly when aiming to preserve the principles of immutability and purity that are central in such settings.

To address this, we first turned to linear type systems (Chapter 1). From their foundations in (linear) logic to their modern formulations and implementations, we examined how linear types can be leveraged to ensure that a resource will only be used exactly once.

With linear types in place, we set out to formalize destination passing within a functional model, called  $\lambda_d$  (Chapter 2). The core idea is that a destination —a pointer to a yet-unused memory cell— must be used exactly once. Once used, the corresponding memory cell becomes readable, and the value contained within is now guaranteed not to change (to abide by immutability). Consequently, the main invariant is that a destination should always point to an existing hole (a yet unused memory cell), and that every remaining hole in a structure must be referenced by exactly one destination that hasn't been used yet. Destinations acts as both witnesses and a way of filling those holes, and when no destination remains, the structure should be fully initialized and contain no remaining holes.

Early on this journey however, we encountered the critical issue of *scope escape*, which required over a year of research to resolve. Scope escape (Section 2.3) arises when a destination is used to store another destination. Even under a strict linear discipline, the type system cannot always distinguish whether a destination has been consumed, meaning the associated memory

cell contains a valid value; or if the destination has been merely stored for later use, in which case reading the corresponding memory cell prematurely may cause a segmentation fault or a similar memory error.

To address this, we had to strengthen the type system of  $\lambda_d$  by introducing a *system of ages* alongside linearity to ensure memory safety. Fortunately, in Section 1.4, we had already developed a modal presentation of linear type systems, structured around an underlying semiring algebra, that is well suited for easy extension. In particular, this allowed us to integrate both the linear and age systems into a same semiring, hence the resulting type system for  $\lambda_d$  (Section 2.5) remains close in spirit to earlier work, while addressing the additional safety concerns posed by scope escape.

In  $\lambda_d$ , the main additions compared to a standard  $\lambda$ -calculus are ampars —structures that may be partially constructed and contain holes— and destinations, which are linearly tracked pointers to these holes. While holes themselves are not first-class citizens of the language, unlike destinations, they play a crucial role in both typing and semantics. In particular, we introduced a new typing discipline for structures with holes (Section 2.6.1). Both the holes within an ampar and its associated destinations are represented as named bindings in the typing context. A hole and a destination with the same name cancel each other out. As a result, a fully constructed ampar has an empty typing context, while a non-empty context indicates either an unfilled hole or a destination referencing an already-filled one. This is how we ensure, within the type system, that no destination can be reused or forgotten.

The operational semantics of  $\lambda_d$  (Section 2.6.3) relies on a rather abstract memory model, in which program state is purely defined by the evaluation context and the term under focus. Memory writes triggered by the action of filling a destination are modeled as global substitutions on named holes within the evaluation context. This semantic model is simpler than conventional store-based semantics, as typing rules for evaluation contexts are direct extensions of those for terms, whereas store semantics typically require more complex typing machinery. Despite its simplicity, this approach faithfully captures the behavior of destination-induced memory mutations.

A key contribution of this work is that we were able to formalize  $\lambda_d$  in the Coq proof assistant (Section 2.7) and then produce a mechanically verified proof of the usual safety theorems for  $\lambda_d$ , namely *progress* and *preservation*.

With  $\lambda_d$ , we thus obtain a formal functional language with destination passing embedded so deeply in its core that we have maximal flexibility in using destinations. For example, standard data constructors are not required as primitive elements of the language, as they can be reconstructed using destination-filling operations. This expressive power, however, comes at the cost of requiring a custom type system to ensure safety.

Thus, the second, and equally important part of the PhD —especially since the PhD is funded by a company with industrial functional programming in its DNA— consisted in porting the core ideas of  $\lambda_d$  and destination passing into the setting of a practical, industrial functional programming language. Haskell was a natural choice for this, due to its existing support for linear types. Even more so since my industrial supervisor, Arnaud SPIWACK, is one of the authors of Linear Haskell [Bernardy et al., 2018; Spiwack et al., 2022] and a strong proponent of improving linear type support and ergonomics within GHC. The main challenge in implementing destination passing in Haskell is that we cannot rely on the custom type system of  $\lambda_d$ , based on both linearity and ages, to guarantee safety. Instead, we must rely on linearity alone.

Initial experiments with destination-passing style programming in Haskell actually predate the theoretical development of  $\lambda_d$ . At that time, scope escape was still an open problem, with no solution yet in sight (so the age system had not been introduced either). As a result, in the meantime, we began developing a prototype API for destination passing in Haskell (Chapter 3), where scope escape is ruled out by design: we chose to forbid storing destinations inside other destinations as a safety measure. A major concern for the implementation was to avoid mutations (for destination-filling operations) that could disrupt Haskell’s memory model. To address this, we used *compact regions*—memory areas outside the reach of the garbage collector—in which unfinished data structures could live without troubles. This practical work ultimately spanned from designing a consistent and ergonomic high-level API down to implementing low-level compiler primitives representing destination-filling operations. The resulting benchmarks (Section 3.6) are encouraging: destination passing proves to be a valuable tool in specific scenarios, improving the performance of some functional programs and enabling more direct, imperative-style code when desired, without compromising memory safety. However, further work is needed to improve both the ergonomics and performance of the DPS implementation if we want it to gain broader adoption in the functional programming community.

One inconvenience with DPS Haskell, in the form presented in Chapter 3, is the restriction we imposed initially—that destinations cannot store any linear resource to avoid scope escape. It impedes the flexibility and expressivity gains that we claimed true for  $\lambda_d$ . In particular, one of our motivating examples, breadth-first traversal of a tree, cannot be implemented using our destination-passing toolkit alone in this first version of DPS Haskell: at some point, we have no choice than to fall back to standard Haskell data structures rather than relying exclusively on the destination-based structures.

In Chapter 4, we attempt to recover much of the lost expressivity. However, relaxing the safety constraint that destinations cannot be filled with linear resources requires great care to avoid scope escape and other issues that arise in the absence of ages (and age control). Still, by the end of this effort, we obtain a way to write our favorite breadth-first tree traversal using only destination-based data structures, in Haskell, through an API we believe to be safe.

Further work would consist in verifying the safety of both the original and extended DPS Haskell APIs developed in Chapters 3 and 4. We have argued that  $\lambda_d$  provides a framework to reason about the safety and correctness of destination-passing systems—now would be the time to put that claim to the test.

A second direction for improvement is to implement DPS support for Haskell within the garbage-collected heap (that is, the standard memory region where most Haskell data resides) rather than relying on the protective shell of compact regions. The challenge here lies in the tight coupling between memory safety and the garbage collector internals, particularly those concerning when and where immutability assumptions are used.

Finally, a third possible improvement would be to extend destination-passing structure building to data structures with unpacked fields—that is, structures where some fields directly embed child elements rather than storing pointers to them. So far, we have only considered destination passing for purely linked structures, and for good reason: this allows efficient composition (i.e., merging) of structures with holes, by simply writing the address of the child structure into the appropriate field of the parent one, in a single memory operation. In contrast, for structures with unpacked fields, the situation is more delicate. A naive deep copy of the child structure would invalidate any existing destinations pointing to it, requiring careful tracking and potentially more complex mechanisms. Supporting such structures would therefore not come for free.

### *Conclusion and future work*

We hope that, by now, the reader has got a good and enjoyable overview of this exotic journey: an exploration of how imperative techniques and functional principles can be reconciled, from high-level and formal considerations to low-level implementation and associated performance concerns. At last, we can say with confidence: safe, functional destination passing is not an oxymoron —it exists!
